A Method of Calculating the Solid Angle Subtended by a Circular Aperture

By Minoru NAITŌ
Department of Physics, University of Akita

(Received March 8, 1957)

Practical formulae in terms of elliptic integrals have been obtained which are useful for calculating the solid angle subtended by a circular aperture at a point which is not on the axis of the aperture. Like the familiar formulae in terms of zonal harmonics, these formulae can be used not only to calculate the solid angle with an accuracy of 4 significant figures, but are also applicable to cases in which the former formulae cannot be employed owing to their slow rate of convergence. The results of some preliminary calculations are shown in tables.

§ 1. Introduction

As is well known, the solid angle Ω_P subtended by an aperture at any point P is given by the expression

$$\Omega_P=\iint_S \frac{\cos\gamma}{R^2}\,dS\,, \qquad (1)$$

where S is a surface bounded by the aperture, R is the distance from P to a point Q on the surface, and γ is the angle between the normal to the surface element dS at Q and the line PQ (Fig. 1).

Such a solid angle occurs in various branches of physics, e.g. in the radiation or radioactivity measurements, in the calculation of magnetic potential produced by a current, the mutual inductance, etc. Especially, in radiation physics circular apertures appear very commonly, and the ratio of the solid angle subtended by the aperture Ω_P to 4π is often called the "geometrical factor" G_P of the aperture:

$$G_P=\Omega_P/(4\pi) \tag{2}$$

Even for a simple case of a circular aperture, Ω_P or G_P cannot be expressed in a simple closed form unless the point P lies on the axis of the aperture. Many workers[1)-4)] have already given various approximate and practical formulae for facilitating the calculation of the solid angle, e.g. those in terms of binomial series, zonal harmonics and elliptic integrals, and the formulae in terms of zonal harmonics* seem to have been used most usually.

Recently, Jaffey[2)] and supplementarily Garrett[3)] have presented excellent summary of practical formulae and tables useful for calculating the solid angle. Especially, the latter has pointed out that a formula in terms of elliptic integrals is excellent in its validity in comparison with other formulae. The object of the present work is to investigate the behaviours of such a formula. First, the writer has derived analytically a reasonable formula by carrying out exact calculation of Ω_P in terms of elliptic integrals, and has given a preliminary table as computed by our formulae. Next, he has given supplementarily geometrical interpretations of the parameters appearing in the formulae.

§ 2. Derivation of Exact Solution of Ω_P

Referring to Fig. 1 let ABC be a circular aperture of radius a with its centre at the origin O of the coordinate-axes, and let the cylindrical coordinates of P and Q be $(x, 0, z)$ and $(r, \theta, 0)$ respectively. Then, since

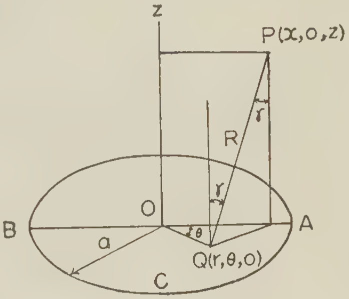

Fig. 1.

$$R^2=z^2+x^2+r^2-2xr\cos\theta\,, \quad \cos\gamma=z/R\,,$$

we have

$$\Omega_P=\int_0^{2\pi}\int_0^a \frac{zrd\theta dr}{(z^2+x^2+r^2-2xr\cos\theta)^{3/2}}\,. \quad (z\neq 0) \tag{3}$$

Carrying out integration with respect to r, we have, after some laborious calculations,

$$\Omega_P=2\pi-\frac{4zK(k)}{[z^2+(a+x)^2]^{1/2}}+2zx\int_0^{\pi}\frac{\cos\theta(a-x\cos\theta)d\theta}{(z^2+x^2\sin^2\theta)[z^2+(a+x)^2-4ax\cos^2\theta/2]^{1/2}}\,, \tag{4}$$

where $K(k)$ represents the complete elliptic integral of the first kind with modulus k given by

$$k^2=4ax/[z^2+(a+x)^2]\,, \tag{5}$$

accordingly its complementary modulus k' being

$$k'^2=1-k^2=[z^2+(a-x)^2]/[z^2+(a+x)^2]\,. \tag{6}$$

Thus, $0\leq k\leq 1$ whenever $x\geq 0$ and $z>0$.

The last integral in (4) can be decomposed into three integrals, one of which gives the same integrals as the second with minus sign and the remaining two are denoted by I_1 and I_2. Changing the integration variable from θ to φ by the relation $\theta=\pi-2\varphi$ we get

---

* The formulae in terms of zonal harmonics are as follows:
When $x<a$

$$\Omega_P=2\pi\left[1-\frac{2}{(z^2+a^2)^{1/2}}+\frac{a^2}{z^2+a^2}\sum_{n=2,4,\dots}^{\infty}\frac{1}{n}P_n(0)P_n'\left(\frac{z}{\sqrt{z^2+a^2}}\right)\left(\frac{x}{\sqrt{z^2+a^2}}\right)^n\right],$$

and when $x>a$

$$\Omega_P=-2\pi\sum_{n=2,4,\dots}^{\infty}P_n(0)P_{n-1}\left(\frac{z}{\sqrt{z^2+x^2}}\right)\left(\frac{a}{\sqrt{z^2+x^2}}\right)^n.$$

$$\Omega_P = 2\pi + I_1 + I_2 \,, \tag{7}$$

where

$$I_1 = \frac{-2z[(z^2+x^2)^{1/2}-a]}{[(z^2+x^2)^{1/2}+x]\,[z^2+(a+x)^2]^{1/2}} \int_0^{\pi/2} \frac{d\varphi}{(1-\lambda_1{}^2\sin^2\varphi)(1-k^2\sin^2\varphi)^{1/2}} \,, \tag{8}$$

$$I_2 = \frac{-2z[(z^2+x^2)^{1/2}+a]}{[(z^2+x^2)^{1/2}-x]\,[z^2+(a+x)^2]^{1/2}} \int_0^{\pi/2} \frac{d\varphi}{(1+\lambda_2{}^2\sin^2\varphi)(1-k^2\sin^2\varphi)^{1/2}} \,, \tag{9}$$

with

$$\lambda_1{}^2 = 2x/[(z^2+x^2)^{1/2}+x] \,, \qquad \lambda_2{}^2 = 2x/[(z^2+x^2)^{1/2}-x] \,. \tag{10}$$

In order to evaluate the above two integrals I_1 and I_2, let us introduce two constant parameters α and β such that

$$k^2 \operatorname{sn}^2\alpha = \lambda_1{}^2 \,, \qquad k^2 \operatorname{sn}^2\beta = -\lambda_2{}^2 . \tag{11}$$

In general α and β will take complex values (see (A.6), (A.7)).

Then both I_1 and I_2 can be reduced to the fundamental complete elliptic integrals of the third kind by the substitution $\sin\varphi = \operatorname{sn}\xi$, and referring to (A.18) in Appendix, we have

$$I_1 = \frac{-2i \operatorname{cn}\alpha \operatorname{dn}\alpha K(k)}{\operatorname{sn}\alpha} - 2i\Pi(K,\, \alpha,\, k) \,, \tag{12}$$

$$I_2 = \frac{-2i \operatorname{cn}\beta \operatorname{dn}\beta K(k)}{\operatorname{sn}\beta} - 2i\Pi(K,\, \beta\ k) \,, \tag{13}$$

where $\Pi(K, \alpha, k)$ and $\Pi(K, \beta, k)$ are the complete elliptic integrals of the third kind with modulus k, amplitude $K(k)$ and parameters α and β respectively, namely:

$$\left.\begin{aligned} \Pi(K,\, \alpha,\, k) &= k^2 \operatorname{sn}\alpha \operatorname{cn}\alpha \operatorname{dn}\alpha \int_0^K \frac{\operatorname{sn}^2\xi\, d\xi}{1-k^2\operatorname{sn}^2\alpha\operatorname{sn}^2\xi} \,, \\ \Pi(K,\, \beta,\, k) &= k^2 \operatorname{sn}\beta \operatorname{cn}\beta \operatorname{dn}\beta \int_0^K \frac{\operatorname{sn}^2\xi\, d\xi}{1-k^2\operatorname{sn}^2\beta\operatorname{sn}^2\xi} \,. \end{aligned}\right\} \tag{14}$$

If we use the well-known relation:

$$\Pi(u,\, a,\, k) - \Pi(a,\, u,\, k) = uE(a,\, k) - aE(u,\, k) \,,$$

where $E(a, k)$ and $E(u, k)$ represent elliptic integrals of the second kind, these integrals can be written in the forms:

$$\Pi(K,\, \alpha,\, k) = K(k)E(\alpha,\, k) - \alpha E(k) \,, \qquad \Pi(K,\, \beta,\, k) = K(k)E(\beta,\, k) - \beta E(k) \,. \tag{15}$$

Thus, (7) becomes

$$\Omega_P = 2\pi - 2i\left[\left(\frac{\operatorname{cn}\alpha\operatorname{dn}\alpha}{\operatorname{sn}\alpha} + \frac{\operatorname{cn}\beta\operatorname{dn}\beta}{\operatorname{sn}\beta}\right)K(k) + \Pi(K,\, \alpha,\, k) + \Pi(K,\, \beta,\, k)\right], \tag{16}$$

which, by the use of the relation[5)]

$$\Pi(K,\, \alpha,\, k) + \Pi(K,\, \beta,\, k) = \Pi(K,\, \alpha+\beta,\, k) + k^2K(k)\operatorname{sn}\alpha\operatorname{sn}\beta\operatorname{sn}(\alpha+\beta) \,,$$

as well as the relation like (15), may be changed into

$$\Omega_P = 2\pi - 2i\left[\frac{\operatorname{sn}(\alpha+\beta)}{\operatorname{sn}\alpha\operatorname{sn}\beta}K(k) + K(k)E(\alpha+\beta,\, k) - (\alpha+\beta)E(k)\right]. \tag{17}$$

Making use of the imaginary transformation[6)] of $E(u)$ and referring to (A.19), (A.20) and (A.21) in Appendix, the second and third terms in the parenthesis of Eq. (17) are written in a more practical form containing real parameters alone, namely:

$$K(k)E(\alpha+\beta,\, k)-(\alpha+\beta)E(k)=i[w\{K(k)-E(k)\}-K(k)E(w,\, k)+k'^2K(k)\,\overline{\mathrm{sn}}\,w\,\overline{\mathrm{cn}}\,w/\overline{\mathrm{dn}}\,w] \tag{18}$$

Here w is a new real constant parameter introduced in place of $\alpha+\beta$ (see Appendix), and $\overline{\mathrm{sn}}\,w$, $\overline{\mathrm{cn}}\,w$ and $\overline{\mathrm{dn}}\,w$ represent Jacobi's elliptic functions with the complementary modulus k'. Thus, we arrive at a final result (the first formula):

$$\begin{aligned}\Omega_{\mathrm{P}}&=2\pi+2[w\{K(k)-E(k)\}-K(k)E(w,\, k')-k'K(k)\,\overline{\mathrm{sn}}\,w]\\&=2\pi+2[F(\phi,\, k')\{K(k)-E(k)\}-K(k)E(\phi,\, k')-k'K(k)\sin\phi]\,,\end{aligned} \tag{19}$$

where, by means of (A.16), the real constant parameter w has been replaced by the elliptic integral of the first kind:

$$w=\int_0^\phi \frac{d\theta}{(1-k'^2\sin^2\theta)^{1/2}}=F(\phi,\, k')\,, \tag{20}$$

or

$$\overline{\mathrm{sn}}\,w=\sin\phi=z/[z^2+(a-x)^2]^{1/2} \qquad \text{(see (A.17))}\,. \tag{21}$$

In the above calculations we have made no restriction to variables except $x\geqq 0$, $z>0$. Therefore, the formula (19) is applicable to any values of x and z such that $x\geqq 0$, $z>0$, so that this is also applicable to the cases of $x=a$ and $(z^2+x^2)^{1/2}=a$, or $(z^2+a^2)^{1/2}=x$, where the usual formula in terms of zonal harmonics is of poor convergence. When $x=a$, with the aid of the well-known formula

$$E(k)K(k')+K(k)E(k')-K(k)K(k')=\pi/2\,, \tag{22}$$

the formula (19) is reduced to a very simple form:

$$\Omega_{\mathrm{P}}=\pi-2k'K(k)\,. \tag{23}$$

Next, we shall derive from the first formula (19) a more interesting and practically applicable formula by applying Landen's transformation[5),6)], by which we have

$$F(\phi,\, k')=2F(\phi_1,\, k_1')/(1+k')\,, \tag{24}$$

$$E(\phi,\, k')=(1+k')\{E(\phi_1,\, k_1')+(1-k')F(\phi_1,\, k_1')/(1+k')\}-k'\sin\phi\,, \tag{25}$$

$$K(k)=2K(k_1)/(1+k')\,, \tag{26}$$

$$E(k)=(1+k')E(k_1)-2k'K(k_1)/(1+k')\,, \tag{27}$$

with

$$k_1=(1-k')/(1+k')\,, \qquad k_1'=2\sqrt{k'}/(1+k')\,, \tag{28}$$

where ϕ_1 represents the amplitude of the elliptic integral with new modulus k_1' and is related with the amplitude ϕ of the elliptic integral (20) by the equation:

$$\tan\phi=\sin 2\phi_1/(k'+\cos 2\phi_1) \qquad \text{or} \qquad \tan(\phi-\phi_1)=k_1\tan\phi_1\,. \tag{29}$$

Putting (24)∼(27) into (19), we have a formula (the second formula):

$$\Omega_{\mathrm{P}}=2\pi+4[F(\phi_1,\, k_1')\{K(k_1)-E(k_1)\}-K(k_1)E(\phi,\, k_1')]\,, \tag{30}$$

with

$$k_1=\frac{1-k'}{1+k'}=\frac{[z^2+(a+x)^2]^{1/2}-[z^2+(a-x)^2]^{1/2}}{[z^2+(a+x)^2]^{1/2}+[z^2+(a-x)^2]^{1/2}}\,, \tag{31}$$

$$k_1'=\frac{2\sqrt{k'}}{1+k'}=\frac{2[z^2+(a+x)^2]^{1/4}[z^2+(a-x)^2]^{1/4}}{[z^2+(a+x)^2]^{1/2}+[z^2+(a-x)^2]^{1/2}}\,, \tag{32}$$

$$\sin^2\phi_1=\frac{z^2+x^2-a^2+[z^2+(a+x)^2]^{1/2}[z^2+(a-x)^2]^{1/2}}{2[z^2+(a+x)^2]^{1/2}[z^2+(a-x)^2]^{1/2}}\,. \tag{33}$$

According to Garrett[3], this result is identical with that by Tallqvist[4]. It will readily b proved that when $x \geqq 0$, $z > 0$ the inequality:

$$F(\phi_1, k_1')\{K(k_1) - E(k_1)\} < K(k_1)E(\phi_1, k_1')$$

always holds so that the second term in (30) is negative.

§ 3. An Asymptotic Formula for Ω_P

By repeating Landen's transformations n—1 times more successively, we have from (30

$$\Omega_P = 2\pi + 2^{n+1}[F(\phi_n, k_n')\{K(k_n) - E(k_n)\} - K(k_n)E(\phi_n, k_n')] \\ +4[k_1'K(k_1)\sin\phi_1 + 2k_2'K(k_2)\sin\phi_2 + \cdots + 2^{n-2}k_{n-1}'K(k_{n-1})\sin\phi_{n-1}] , \qquad (34$$

where $k_1, k_2, \cdots, k_n, k_1', k_2', \cdots, k_n'$ are moduli such that $k_n \to 0$, $k_n' \to 1$ as $n \to \infty$ and ϕ_1, $\cdots, \phi_n$ are parameters such that ϕ_n tends to a definite limit, ϕ_∞ say, as $n \to \infty$.

It will readily be seen that as $k_n \to 0$,

$$K(k_n) - E(k_n) \to 0 ,$$

$$K(k_n)E(\phi_n, k_n') \to \frac{\pi}{2} \sin\phi_n .$$

Thus we obtain finally an asymptotic formula (the third formula) in the form:

$$\Omega_P = 2\pi + 4\left[k_1'K(k_1)\sin\phi_1 + 2k_2'K(k_2)\sin\phi_2 + \cdots + 2^{n-2}k_{n-1}'K(k_{n-1})\sin\phi_{n-1} - 2^{n-1}\frac{\pi}{2}\sin\phi_n \right], \qquad (34$$

and this formula can be conveniently used for calculating Ω_P to 3 or 4 significant figures.

§ 4. Geometrical Meanings of k', k_1, ϕ and ϕ_1

In the first place, it will easily be seen from (6) that referring to Fig. 2 k' is equal to the ratio of the minimum generating line to the maximum one of the cone subtending the solid angle Ω_P with the circular aperture as its base, i.e.

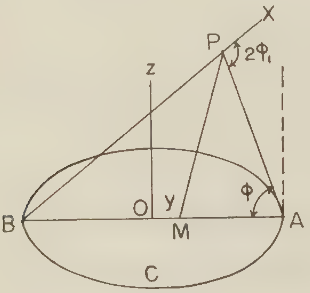

Fig. 2.

$$k' = [z^2 + (a-x)^2]^{1/2} / [z^2 + (a+x)^2]^{1/2} = \mathrm{AP/BP} . \qquad (35)$$

If the point of intersection of the line bisecting the vertex angle $\angle$APB with the diameter AB be denoted by M and let OM$=y$, then we have

$$k_1 = (1-k')/(1+k') = y/a = \mathrm{OM/OA} . \qquad (3$$

Next, it is apparent from (21) that the amplitude ϕ gives the angle between the diamete AB and the minimum generating line AP o the cone. Thus, when $x = a$, ϕ is equal t $\pi/2$ irrespectively of z.

Lastly, we can easily prove by (33) that 2ϕ is the complementary angle of the verte angle $\angle$APB. Thus, it is found that whe $x < a$, $\sin^2\phi_1$ reduces to zero as z decreases whereas when $x > a$, $\sin^2\phi_1$ has a minimu value at $z^2 = x^2 - a^2$ and tends to unity as approaches 0 or ∞.

§ 5. Numerical Computations

Numerical values of the solid angle Ω_P hav been calculated by the third formula (34). Th number of times n of Landen's transformations which should be repeated until k_n' becomes nearly equal to unity within the accuracy of at least 5 figures is different fo different starting values of k'. Table I shows in its second row, such required numbers o times for different starting values of k' a shown in the first row.

The starting values of k and k' can be ob tained by the geometry. Thus, for example, when $x=z=a$, we have, by (5) and (6),

$$k=0.8944272\ ,\quad k'=0.4472136\ .$$

An example of numerical calculations for the case in which $x=z=a$ is shown in Table II.

Table I.

k'	10^{-4}	10^{-2}	0.1	0.2	0.7	0.8	0.95	0.994
n	5	4	4	3	3	2	2	1

Table II.

First stage ($n=0$)	Second stage ($n=1$)	Third stage ($n=2$)	Fourth stage ($n=3$)
$\log k'$ $\bar{1}.6505150$	$\log k_1'$ $\bar{1}.9657549$	$\log k_2'$ $\bar{1}.9996626$	$\log k_3'$ 0
$\log K(k)$ 0.3535710	$\log K(k_1)$ 0.2130736	$\log K(k_2)$ 0.1962885	$\log K(k_3)$ 0.1961198
$\log \sin \phi$ 0	$\log \sin \phi_1$ $\bar{1}.9297513$	$\log \sin \phi_2$ $\bar{1}.9136557$	$\log \sin \phi_3$ $\bar{1}.9134871$
$\log \cos \phi$ $-\infty$	$\log \cos \phi_1$ $\bar{1}.7207637$	$\log \cos \phi_2$ $\bar{1}.7579962$	
$\log(1+k'/2)$ $\bar{1}.8595026$	$\log(1+k_1'/2)$ $\bar{1}.9832149$	$\log(1+k_2'/2)$ $\bar{1}.9998313$	

The values of the complete elliptic integrals $K(k)$, $K(k_1)$, etc. have been calculated conveniently by the formula

$$K(k)=\frac{\pi}{2}\,\frac{2}{1+k_{n-1}'}\cdots\cdots\frac{2}{1+k'}\ ,$$

$$\cdots\cdots$$

$$K(k_{n-1})=\frac{\pi}{2}\,\frac{2}{1+k_{n-1}'}\ .$$

The value of Ω_P in this case when $x=z=a$ has been calculated by an approximate formula:

$$\Omega_P=2\pi-4[k_1'K(k_1)\sin\phi_1 +2k_2'K(k_2)\sin\phi_2-2\pi\sin\phi_3]\ ,$$

and the result is $\Omega_P=1.122689$. This should be compared with the result $\Omega_P=1.122686$ which has been calculated by the use of the formula (23), and also with the result $\Omega_P=1.1225$ as calculated from Jaffey's table[2].

It will be seen that our asymptotic formula (34) can be used with sufficient accuracy for calculating the solid angle Ω_P.

In conclusion, the author wishes to express his hearty thanks to Professor Suekichi Kawata of Konan University for his helpful remarks.

Appendix

Properties of Constant Parameters α, β and Associated Constants

First, let us determine the values of α and β satisfying (11). Among Jacobian elliptic functions of α and β satisfying (11) we may choose the following:

$$\operatorname{sn}\alpha=+\lambda_1/k\ ,\quad \operatorname{sn}\beta=+i\lambda_2/k\ . \tag{A.1}$$

It is apparent from (5) and (10) that the relations $\lambda_1/k\geq 1$ and $\lambda_2/k\geq 1$ hold for any values of x and z except for $z=0$, and therefore $\operatorname{sn}\alpha$ and $\operatorname{sn}\beta$ are restricted respectively to the following ranges, namely:

$$1\leq\operatorname{sn}\alpha<(x+a)/2\sqrt{ax}=[1/k]_{z=0}\ , \tag{A.2}$$

$$1\leq|\operatorname{sn}\beta|<\infty\ . \tag{A.3}$$

Comparing these ranges with the fundamental period-parallelogram of sn functions[5),6)], it will be found that α and β should take the following values:

$$\alpha=K(k)+iu\ ,\quad K(k)+i[K(k')+u]; \tag{A.4}$$

$$\beta=iv\ ,\qquad i[K(k')+v]\ , \tag{A.5}$$

where u and v are both real constant values such that $-K(k')<u<K(k')$, $0<v<K(k')$. Hence, α is a complex constant and β a purely imaginary constant.

As the required values of α and β we may conveniently choose the simplest forms, namely:

$$\alpha=K(k)+iu\ , \tag{A.6}$$

$$\beta=iv\ . \tag{A.7}$$

Thus, we can derive other Jacobian Elliptic functions from the above relations:

$$\left.\begin{aligned}
\operatorname{sn}\alpha&=\operatorname{sn}(K+iu)=\frac{\lambda_1}{k}=\frac{[z^2+(a+x)^2]^{1/2}}{(2a)^{1/2}[(z^2+x^2)^{1/2}+x]^{1/2}}\ ,\\
\operatorname{cn}\alpha&=\operatorname{cn}(K+iu)=\frac{-i(\lambda_1^2-k^2)^{1/2}}{k}=\frac{-i[(z^2+x^2)^{1/2}-a]}{(2a)^{1/2}[(z^2+x^2)^{1/2}+x]^{1/2}}\ ,\\
\operatorname{dn}\alpha&=\operatorname{dn}(K+iu)=(1-\lambda_1^2)^{1/2}=\frac{[(z^2+x^2)^{1/2}-x]^{1/1}}{[(z^2+x^2)^{1/2}+x]^{1/2}}\ ,
\end{aligned}\right\} \tag{A.8}$$

$$\left.\begin{aligned}
\mathrm{sn}\,\beta&=\mathrm{sn}\,iv=\frac{i\lambda_2}{k}=\frac{i[z^2+(a+x)^2]^{1/2}}{(2a)^{1/2}[(z^2+x^2)^{1/2}-x]^{1/2}}\,,\\
\mathrm{cn}\,\beta&=\mathrm{cn}\,iv=\frac{(k^2+\lambda_2{}^2)^{1/2}}{k}=\frac{a+(z^2+x^2)^{1/2}}{(2a)^{1/2}[(z^2+x^2)^{1/2}-x]^{1/2}}\,,\\
\mathrm{dn}\,\beta&=\mathrm{dn}\,iv=(1+\lambda_2{}^2)^{1/2}=\frac{[(z^2+x^2)^{1/2}+x]^{1/2}}{[(z^2+x^2)^{1/2}-x]^{1/2}}\,.
\end{aligned}\right\}\tag{A.9}$$

and from these equations we can easily determine the forms of u and v, namely:

$$\left.\begin{aligned}
\mathrm{sn}\,u(k')&=\overline{\mathrm{sn}}\,u=\frac{(z^2+x^2)^{1/2}-a}{[z^2+(a-x)^2]^{1/2}}\,,\\
\mathrm{cn}\,u(k')&=\overline{\mathrm{cn}}\,u=\frac{(2a)^{1/2}[(z^2+x^2)^{1/2}-x]^{1/2}}{[z^2+(a-x)^2]^{1/2}}\,,\\
\mathrm{dn}\,u(k')&=\overline{\mathrm{dn}}\,u=\frac{(2a)^{1/2}[(z^2+x^2)^{1/2}+x]^{1/2}}{[z^2+(a-x)^2]^{1/2}}\,,
\end{aligned}\right\}\tag{A.10}$$

$$\left.\begin{aligned}
\mathrm{sn}\,v(k')&=\overline{\mathrm{sn}}\,v=\frac{[z^2+(a+x)^2]^{1/2}}{(z^2+x^2)^{1/2}+a}\,,\\
\mathrm{cn}\,v(k')&=\overline{\mathrm{cn}}\,v=\frac{(2a)^{1/2}[(z^2+x^2)^{1/2}-x]^{1/2}}{(z^2+x^2)^{1/2}+a}\,,\\
\mathrm{dn}\,v(k')&=\overline{\mathrm{dn}}\,v=\frac{(2a)^{1/2}[(z^2+x^2)^{1/2}+x]^{1/2}}{(z^2+x^2)^{1/2}+a}\,.
\end{aligned}\right\}\tag{A.11}$$

If we denote the amplitudes of the elliptic integrals of u and v by ψ_1 and ψ_2 respectively we have

$$\left.\begin{aligned}
\sin\psi_1&=\frac{(z^2+x^2)^{1/2}-a}{[z^2+(a-x)^2]^{1/2}}\,,\\
\sin\psi_2&=\frac{[z^2+(a+x)^2]^{1/2}}{(z^2+x^2)^{1/2}+a}\,.
\end{aligned}\right\}\tag{A.12}$$

Next, we consider elliptic functions of $\alpha+\beta$. By means of the addition theorem for the Jacobian functions[5),6)] and Jacobi's imaginary transformation[5),6)], we get

$$\left.\begin{aligned}
\mathrm{sn}\,(\alpha+\beta)&=\mathrm{sn}\,(K+i(u+v))=\mathrm{cn}\,iw/\mathrm{dn}\,iw=1/\overline{\mathrm{dn}}\,w=[z^2+(a+x)^2]^{1/2}/(a+x)\,,\\
\mathrm{cn}\,(\alpha+\beta)&=\mathrm{cn}\,(K+i(u+v))=-k'\,\mathrm{sn}\,iw/\mathrm{dn}\,iw=-ik'\,\overline{\mathrm{sn}}\,w/\overline{\mathrm{dn}}\,w=-iz/(a+x)\,,\\
\mathrm{dn}\,(\alpha+\beta)&=\mathrm{dn}\,(K+i(u+v))=k'/\mathrm{dn}\,iw=k'\,\overline{\mathrm{cn}}\,w/\overline{\mathrm{dn}}\,w=(a-x)/(a+x)\,,
\end{aligned}\right\}\tag{A.13}$$

where $w=u+v$ is given by

$$\alpha+\beta=K(k)+iw\,.\tag{A.14}$$

Thus, we finally obtain

$$\overline{\mathrm{sn}}\,w=\frac{z}{[z^2+(a-x)^2]^{1/2}}\,,\qquad \overline{\mathrm{cn}}\,w=\frac{a-x}{[z^2+(a-x)^2]^{1/2}}\,,\qquad \overline{\mathrm{dn}}\,w=\frac{a+x}{[z^2+(a+x)^2]^{1/2}}\,,\tag{A.15}$$

and consequently, w can be written in the form:

$$w=\int_0^{\phi}\frac{d\theta}{(1-k'^2\sin^2\theta)^{1/2}}=F(\phi,\,k')\,,\tag{A.16}$$

where ϕ is the amplitude of the elliptic integral of w, so that

$$\left.\begin{aligned} \overline{\mathrm{sn}}\, w = \sin\phi &= \frac{z}{[z^2+(a-x)^2]^{1/2}}\,, \\ \overline{\mathrm{cn}}\, w = \cos\phi &= \frac{a-x}{[z^2+(a-x)^2]^{1/2}}\,, \end{aligned}\right\} \tag{A.17}$$

Further, a few results will be given which are useful for the calculation of the solid angle Ω_P in § 2.

(i) By the help of (A.8) and (A.10) the terms in front of the integrals in (8) and (9) may be rewritten in terms of the constant parameters α and β as:

$$\frac{z[(z^2+x^2)^{1/2}-a]}{[(z^2+x^2)^{1/2}+x][z^2+(a+x)^2]^{1/2}} = \frac{i\,\mathrm{cn}\,\alpha\,\mathrm{dn}\,\alpha}{\mathrm{sn}\,\alpha}\,, \quad \frac{z[(z^2+x^2)^{1/2}+a]}{[(z^2+x^2)^{1/2}-x][z^2+(a+x)^2]^{1/2}} = \frac{i\,\mathrm{cn}\,\beta\,\mathrm{dn}\,\beta}{\mathrm{sn}\,\beta}\,. \tag{A.18}$$

(ii) By (A.8), (A.9) and (A.13) we have

$$\frac{\mathrm{sn}\,(\alpha+\beta)}{\mathrm{sn}\,\alpha\;\mathrm{sn}\,\beta} = \frac{k'^2\,\overline{\mathrm{sn}}\,w\,\overline{\mathrm{cn}}\,w + k'\,\overline{\mathrm{sn}}\,w\,\overline{\mathrm{dn}}\,w}{\mathrm{i}\,\overline{\mathrm{dn}}\,w}\,. \tag{A.19}$$

(iii) According to (A.14), $E(iw)$ and $E(\alpha+\beta)$ may be evalualed in terms of the elliptic integrals with real amplitude ϕ. Thus,

$$E(iw) = i[w - E(w,\, k') + \overline{\mathrm{sn}}\,w\,\overline{\mathrm{dn}}\,w/\overline{\mathrm{cn}}\,w]\,, \tag{A.20}$$

$$\begin{aligned} E(\alpha+\beta) &= E(K+iw) = E(iw) + E(k) - ik^2\,\overline{\mathrm{sn}}\,w\,\overline{\mathrm{dn}}\,w/\overline{\mathrm{cn}}\,w \\ &= i[F(\phi,\, k') - E(\phi,\, k') + k'^2\,\overline{\mathrm{sn}}\,w\,\overline{\mathrm{cn}}\,w/\overline{\mathrm{dn}}\,w] + E(k)\,. \end{aligned} \tag{A.21}$$

(iv) With the aid of (A.17) the amplitude relation (29) in Landen's transformation may be rewritten in a convenient form as:

$$\cos 2\phi_1 = -k'\,\overline{\mathrm{sn}}^2\,w + \overline{\mathrm{cn}}\,w\,\overline{\mathrm{dn}}\,w\,, \tag{A.22}$$

$$\begin{aligned} \sin^2\phi_1 &= \frac{1}{2}\left(1 + k'\,\overline{\mathrm{sn}}^2\,w - \overline{\mathrm{cn}}\,w\,\overline{\mathrm{dn}}\,w\right) \\ &= \frac{1}{2}\,(1 + k'\sin^2\phi - \cos\phi\sqrt{1-k'^2\sin^2\phi})\,. \end{aligned} \tag{A.23}$$

Viscous Flows past a Spheroid

By Shōichi WAKIYA

Faculty of Engineering, Niigata University, Nagaoka

(Received June 24, 1957)

A solution of the Stokes equations of motion of a viscous fluid is given in a form suitable for dealing with the flows past an ellipsoid. When the ellipsoid has rotational symmetry, the solution is expressed in infinite triple integrals.

By utilizing these results, two kinds of steady flows of a viscous fluid past a spheroid are studied when the direction of the main stream is parallel to the axis of symmetry of the spheroid. The first is the flow past a spheroid between two parallel plane walls and the second is the flow past a spheroid in a cylindrical pipe with its axis of revolution along the axis of the pipe.

In particular, the drag and the moment acting on the spheroid as well as the pressure drop in the pipe are discussed in detail. It is worth noticing that the moment of force acting on a spheroid moving uniformly between two parallel walls changes its sign when the rate of roundness of the spheroid exceeds a certain definite value.

§ 1. Introduction

The method by which Faxén has studied the effect of boundary walls upon the steady translation of a sphere in a viscous fluid was recently applied to the investigation of the flow of a viscous fluid past a sphere placed in a cylindrical pipe[2),5)] or between two parallel plane walls[3)]. No discussion on other similar problems in the three-dimensional case seems to have been made yet, however. In this paper, boundary-value problems for a spheroid will be treated.

In the first place, Oberbeck's solution[4)] of Stokes' equations of a viscous flow past an ellipsoid is extended to the case of more general fields of flow and then the infinite integral expression of the solution is given for the special case of an ellipsoid of revolution. Next, by making use of this solution, two kinds of steady flows of a viscous fluid past a spheroid are discussed; the first is the flow past a spheroid between two parallel plane walls and the second is the flow past a spheroid in a cylindrical pipe. The drag and the moment acting on the spheroid as well as the pressure drop in the pipe are discussed with special reference to the cases of a circular plate and a sphere.

§ 2. Solution for the Flows round an Ellipsoid

Referring to the rectangular coordinates (x, y, z), Stokes' equations for the steady motion of an incompressible viscous fluid are expressed as follows:

$$\frac{\partial p}{\partial x}=\mu\nabla^2 u\,,\quad \frac{\partial p}{\partial y}=\mu\nabla^2 v\,,\quad \frac{\partial p}{\partial z}=\mu\nabla^2 w\,, \tag{2.1}$$

where $\nabla^2=\partial^2/\partial x^2+\partial^2/\partial y^2+\partial^2/\partial z^2$, μ is the coefficient of viscosity of the fluid, p is the pressure and u, v, w are the velocity components. The equation of continuity is

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}=0\,. \tag{2.2}$$

The coordinate system may be so chosen that the fixed or uniformly moving ellipsoid is given by

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}=1\,. \qquad (a,\ b,\ c\text{: constants}) \tag{2.3}$$

Now, we may construct the solutions of (2.1) and (2.2) which are regular outside of the ellipsoid (2.3) and vanish at infinity, by the aid of the harmonic functions defined by

$$\chi_n=\int_\lambda^\infty \frac{1}{2^n}\left(\frac{x^2}{a^2+s}+\frac{y^2}{b^2+s}+\frac{z^2}{c^2+s}-1\right)^n \frac{ds}{\sqrt{(a^2+s)(b^2+s)(c^2+s)}}, \qquad (n=0,\ 1,\ 2,\ \cdots) \tag{2.4}$$

where $\lambda(x, y, z)$ is a positive root of

$$\frac{x^2}{a^2+\lambda}+\frac{y^2}{b^2+\lambda}+\frac{z^2}{c^2+\lambda}=1\,. \tag{2.5}$$

In particular, we shall use here the following solution:

$$\left.\begin{aligned}
u_1=&\frac{\partial}{\partial x}\left\{Ax\chi_0+C\frac{\partial}{\partial z}(x\chi_1)+\frac{1}{2}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)(x\chi_2)\right\}-2A\chi_0-G\frac{\partial^2\chi_2}{\partial x^2}\\
&-\frac{\partial^2}{\partial x^2}\left\{a^2A\chi_1+\frac{1}{2}\left(F+a^2C\frac{\partial}{\partial z}\right)\chi_2+\frac{a^2}{6}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)\chi_3\right\}\\
&-\frac{\partial}{\partial z}\left\{(B+C)\chi_1+\frac{1}{2}(D+E)\frac{\partial\chi_2}{\partial z}\right\},\\
v_1=&\frac{\partial}{\partial y}\left\{Ax\chi_0+C\frac{\partial}{\partial z}(x\chi_1)+\frac{1}{2}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)(x\chi_2)\right\}\\
&-\frac{\partial^2}{\partial x\partial y}\left\{a^2A\chi_1+\frac{1}{2}\left(F+a^2C\frac{\partial}{\partial z}\right)\chi_2+\frac{a^2}{6}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)\chi_3\right\},\\
w_1=&\frac{\partial}{\partial z}\left\{Ax\chi_0+C\frac{\partial}{\partial z}(x\chi_1)+\frac{1}{2}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)(x\chi_2)\right\}\\
&-\frac{\partial^2}{\partial x\partial z}\left\{a^2A\chi_1+\frac{1}{2}\left(F+a^2C\frac{\partial}{\partial z}\right)\chi_2+\frac{a^2}{6}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)\chi_3\right\}\\
&+\frac{\partial}{\partial x}\left\{(B-C)\chi_1+\frac{1}{2}(D-E)\frac{\partial\chi_2}{\partial z}\right\},\\
p_1=&2\mu\frac{\partial}{\partial x}\left\{A\chi_0+C\frac{\partial\chi_1}{\partial z}+\frac{1}{2}\left(E\frac{\partial^2}{\partial z^2}+G\frac{\partial^2}{\partial x^2}\right)\chi_2\right\},
\end{aligned}\right\} \tag{2.6}$$

with arbitrary constants $A,\ B,\ C,\ \cdots$.

Further we assume that there exists an external flow which tends to the form:

$$\left.\begin{aligned}
u_0&=a_0+a_1z+a_2z^2+a_3x^2\,,\\
v_0&=b_2xy\,,\\
w_0&=c_1x+c_2xz\,.
\end{aligned}\right\} \tag{2.7}$$

on the surface of the ellipsoid (2.3), where the constants a_n, b_n, c_n may have some relations with a, b and c. The boundary conditions: $u=v=w=0$ on the ellipsoid can be satisfied by (2.6) and (2.7) with properly chosen constants. Namely, in terms of a_n, b_n, c_n we have

$$A=\frac{1}{K+a^2L_1}\left\{a_0+\frac{1}{3}(c^2a_2+a^2a_3)\right\},\qquad B=\frac{c^2a_1-a^2c_1}{a^2L_1+c^2L_3},\qquad C=\frac{a_1L_1+c_1L_3}{(a^2L_1+c^2L_3)M_3},\ \cdots \tag{2.8}$$

where

$$\left.\begin{aligned}
K&=\int_0^\infty\frac{ds}{\sqrt{(a^2+s)(b^2+s)(c^2+s)}}\,, & L_1&=\int_0^\infty\frac{ds}{(a^2+s)\sqrt{(a^2+s)(b^2+s)(c^2+s)}}\,,\\
L_3&=\int_0^\infty\frac{ds}{(c^2+s)\sqrt{(a^2+s)(b^2+s)(c^2+s)}}\,, & M_3&=\int_0^\infty\frac{ds}{(a^2+s)(c^2+s)\sqrt{(a^2+s)(b^2+s)(c^2+s)}}\,.
\end{aligned}\right\} \tag{2.9}$$

If a_n, b_n, c_n involve A, B, C, $\cdots$, (2.8) may be regarded as a set of infinite simultaneous equations for determining the constants A, B, C, $\cdots$.

We put $a_3=a_3^*+a_3^{**}(c^2-a^2)/a^2$ and assume that a_1, a_2, b_2, c_1, c_2 and a_3^*, a_3^{**} have all definite values for $a\to 0$. The values in (2.8) reduce to

$$\left.\begin{aligned} A&=\frac{c}{\pi}\left\{a_0+\frac{c^2}{3}(a_2+a_3^{**})\right\}, & B&=C=\frac{2}{\pi}c^3a_1\,, \\ D&=E=\frac{8}{3\pi}c^5a_2\,, & F&=2G=\frac{4}{3\pi}c^5(a_2+2a_3^{**})\,, \end{aligned}\right\} \tag{2.8a}$$

for a circular plate ($a=0$, $b=c$), and

$$\left.\begin{aligned} A&=\frac{3}{8}a\left\{a_0+\frac{a^2}{3}(a_2+a_3^*)\right\}, & B&=\frac{3}{4}a^3(a_1-c_1)\,, & C&=\frac{5}{4}a^3(a_1+c_1)\,, \\ D&=\frac{25}{16}a^5\left(\frac{3}{5}a_2+b_2-c_2\right), & E&=\frac{35}{16}a^5(a_2-b_2+c_2)\,, & & \\ F&=\frac{5}{8}a^5(a_2+3a_3^*+c_2)\,, & G&=\frac{35}{16}a^5(a_3^*-b_2)\,, & & \end{aligned}\right\} \tag{2.8b}$$

for a sphere ($a=b=c$).

The total force on the ellipsoid exerted by the flow given by (2.6) is in the direction of the x-axis and becomes

$$W=16\pi\mu A\,, \tag{2.10}$$

and the moment of force about the centre of the ellipsoid has only the y-component, which is given by

$$N=16\,\pi\mu B\,. \tag{2.11}$$

Finally, in case when the ellipsoid has axial symmetry so that $b=c$ (say), we can express χ_n and $x\chi_n$ in the forms of infinite integrals; among those the followings are utilized in the later analysis.

For $a<c$,

$$\left.\begin{aligned} \chi_0&=\frac{1}{\pi^2}\iiint_{-\infty}^{\infty}\frac{\sin(\sigma\sqrt{c^2-a^2})}{\sigma\sqrt{c^2-a^2}}e^{i(\xi x+\eta y+\zeta z)}\frac{d\xi\,d\eta\,d\zeta}{\rho^2}\,, \\ x\chi_0&=-\frac{2i}{\pi^2}\iiint_{-\infty}^{\infty}\frac{\sin(\sigma\sqrt{c^2-a^2})}{\sigma\sqrt{c^2-a^2}}e^{i(\xi x+\eta y+\zeta z)}\frac{\xi\,d\xi\,d\eta\,d\zeta}{\rho^4}\,, \\ \chi_1&=\frac{1}{\pi^2}\iiint_{-\infty}^{\infty}\left[\frac{\cos(\sigma\sqrt{c^2-a^2})}{(\sigma\sqrt{c^2-a^2})^2}-\frac{\sin(\sigma\sqrt{c^2-a^2})}{(\sigma\sqrt{c^2-a^2})^3}\right]e^{i(\xi x+\eta y+\zeta z)}\frac{d\xi\,d\eta\,d\zeta}{\rho^2}\,, \\ x\chi_1&=-\frac{2i}{\pi^2}\iiint_{-\infty}^{\infty}\left[\frac{\cos(\sigma\sqrt{c^2-a^2})}{(\sigma\sqrt{c^2-a^2})^2}-\frac{\sin(\sigma\sqrt{c^2-a^2})}{(\sigma\sqrt{c^2-a^2})^3}\right]e^{i(\xi x+\eta y+\zeta z)}\frac{\xi\,d\xi\,d\eta\,d\zeta}{\rho^4}\,, \end{aligned}\right\} \tag{2.12}$$

and for $a>c$,

$$\chi_0=\frac{1}{\pi^2}\iiint_{-\infty}^{\infty}\frac{\sin(\xi\sqrt{a^2-c^2})}{\xi\sqrt{a^2-c^2}}e^{i(\xi x+\eta y+\zeta z)}\frac{d\xi\,d\eta\,d\zeta}{\rho^2}\,,$$

$$x\chi_0=-\frac{2i}{\pi^2}\iiint_{-\infty}^{\infty}\left\{\frac{\sin(\xi\sqrt{a^2-c^2})}{\xi\sqrt{a^2-c^2}}-\frac{a^2-c^2}{2}\rho^2\left[\frac{\cos(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^2}-\frac{\sin(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^3}\right]\right\}$$
$$\times e^{i(\xi x+\eta y+\zeta z)}\frac{\xi\,d\xi\,d\eta\,d\zeta}{\rho^4}\,,$$

$$\left.\begin{aligned}\chi_1&=\frac{1}{\pi^2}\iiint_{-\infty}^{\infty}\left[\frac{\cos(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^2}-\frac{\sin(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^3}\right]e^{i(\xi x+\eta y+\zeta z)}\frac{d\xi d\eta d\zeta}{\rho^2},\\ x\chi_1&=-\frac{2i}{\pi^2}\iiint_{-\infty}^{\infty}\left\{\left[\frac{\cos(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^2}-\frac{\sin(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^3}\right]\right.\\ &\qquad\left.+\frac{a^2-c^2}{2}\rho^2\left[\left(1-\frac{3}{(\xi\sqrt{a^2-c^2})^2}\right)\frac{\sin(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^3}+3\frac{\cos(\xi\sqrt{a^2-c^2})}{(\xi\sqrt{a^2-c^2})^4}\right]\right\}\\ &\qquad\qquad\times e^{i(\xi x+\eta y+\zeta z)}\frac{\xi d\xi d\eta d\zeta}{\rho^4},\end{aligned}\right\}\quad(2.12a)$$

where $i=\sqrt{-1}$, $\sigma=\sqrt{\eta^2+\zeta^2}$ and $\rho=\sqrt{\xi^2+\eta^2+\zeta^2}$.

FLOWS PAST A SPHEROID BETWEEN TWO PARALLEL WALLS

§ 3.1. General Formulae

Making use of the above solution (2.6), we shall discuss the flow past a spheroid ($b=c$) placed between two plane walls which are parallel to the xy-plane and are given by

$$z=-d_1,\quad z=d_2\qquad (d_1,\ d_2:\ \text{positive constants})\tag{3.1}$$

respectively.

Suppose that, at large distances from the spheroid, the flow is represented by

$$u_\infty=\alpha+\beta z+\gamma z^2,\quad v_\infty=w_\infty=0,\qquad (\alpha,\ \beta,\ \gamma:\ \text{constants})\tag{3.2}$$

which is a solution of (2.1) and (2.2) with

$$p_\infty=2\mu\gamma x+\text{const.}$$

Then the boundary conditions to be satisfied are

$$u=u_\infty,\qquad v=w=0\qquad \text{at infinity,}\tag{3.3}$$

$$u=v=w=0\qquad \text{for } z=-d_1 \text{ and } z=d_2,\tag{3.4}$$

$$u=v=w=0\qquad \text{on the spheroid.}\tag{3.5}$$

Now, on integration of (2.12) or (2.12a) with respect to ζ, we obtain the following formulae which are valid for both oblate and prolate spheroids, when $|z|>|\varepsilon|$,

$$\begin{aligned}\chi_0&=\frac{1}{\pi}\iint_{-\infty}^{\infty}\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}e^{i(\xi x+\eta y)-k|z|}\frac{d\xi d\eta}{k},\\ x\chi_0&=-\frac{i}{\pi}\iint_{-\infty}^{\infty}\left\{(1+k|z|)\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}-\varepsilon^2k^2\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]\right\}e^{i(\xi x+\eta y)-k|z|}\frac{\xi d\xi d\eta}{k^3},\\ \chi_1&=-\frac{1}{\pi}\iint_{-\infty}^{\infty}\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]e^{i(\xi x+\eta y)-k|z|}\frac{d\xi d\eta}{k},\\ x\chi_1&=\frac{i}{\pi}\iint_{-\infty}^{\infty}\left\{(1+k|z|)\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]\right.\\ &\qquad\left.-\varepsilon^2k^2\left[\left(1+\frac{3}{(\varepsilon\xi)^2}\right)\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}-3\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^4}\right]\right\}e^{i(\xi x+\eta y)-k|z|}\frac{\xi d\xi d\eta}{k^3},\end{aligned}\tag{3.6}$$

where $k=\sqrt{\xi^2+\eta^2}$ and $\varepsilon=\sqrt{c^2-a^2}$ (real or imaginary).

By substituting (3.6) into (2.6), we have when $|z|>|\varepsilon|$

$$\left.\begin{aligned}
u_1&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\left\{f_1+\frac{\xi^2}{k^2}(f_2+k|z|f_3)\right\}e^{i(\xi x+\eta y)-k|z|}\,\frac{d\xi d\eta}{k}\,,\\
v_1&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\frac{\xi\eta}{k^2}(f_2+k|z|f_3)\,e^{i(\xi x+\eta y)-k|z|}\,\frac{d\xi d\eta}{k}\,,\\
w_1&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\frac{z}{|z|}\frac{i\xi}{k}\left\{(f_1+f_3)+(f_2+k|z|f_3)\right\}e^{i(\xi x+\eta y)-k|z|}\,\frac{d\xi d\eta}{k}\,,\\
p_1&=\mu\frac{2}{\pi}\iint\limits_{-\infty}^{\infty}i\xi f_3\,e^{i(\xi x+\eta y)-k|z|}\,\frac{d\xi d\eta}{k}\,,
\end{aligned}\right\}\quad(3.7)$$

where

$$\left.\begin{aligned}
f_1(\xi,\eta)&=-2A\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}-\frac{z}{|z|}(B+C)\,k\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]+\cdots\,,\\
f_2(\xi,\eta)&=A\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}-Ac^2k^2\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]+\cdots\,,\\
f_3(\xi,\eta)&=A\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}+\frac{z}{|z|}Ck\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]+\cdots\,.
\end{aligned}\right\}\quad(3.8)$$

In analogy to (3.7), we can easily verify that another set of solutions of (2.1) and (2.2) is given by

$$\begin{aligned}
u^*&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\left\{g_1+\frac{\xi^2}{k^2}(g_2+kzg_3)\right\}e^{i(\xi x+\eta y)-kz}\,\frac{d\xi d\eta}{k}\,,\\
v^{**}&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\frac{\xi\eta}{k^2}(g_2+kzg_3)\,e^{i(\xi x+\eta y)-kz}\,\frac{d\xi d\eta}{k}\,,\\
w^*&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\frac{i\xi}{k}\left\{(g_1+g_3)+(g_2+kzg_3)\right\}e^{i(\xi x+\eta y)-kz}\,\frac{d\xi d\eta}{k}\,,\\
p^*&=\mu\frac{2}{\pi}\iint\limits_{-\infty}^{\infty}i\xi g_3\,e^{i(\xi x+\eta y)-kz}\,\frac{d\xi d\eta}{k}\,,
\end{aligned}\quad(3.9)$$

and

$$\left.\begin{aligned}
u^{**}&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\left\{h_1+\frac{\xi^2}{k^2}(h_2-kzh_3)\right\}e^{i(\xi x+\eta y)+kz}\,\frac{d\xi d\eta}{k}\,,\\
v^{**}&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\frac{\xi\eta}{k^2}(h_2-kzh_3)\,e^{i(\xi x+\eta y)+kz}\,\frac{d\xi d\eta}{k}\,,\\
w^{**}&=\frac{1}{\pi}\iint\limits_{-\infty}^{\infty}\frac{-i\xi}{k}\left\{(h_1+h_3)+(h_2-kzh_3)\right\}e^{i(\xi x+\eta y)+kz}\,\frac{d\xi d\eta}{k}\,,\\
p^{**}&=\mu\frac{2}{\pi}\iint\limits_{-\infty}^{\infty}i\xi h_3\,e^{i(\xi x+\eta y)+kz}\,\frac{d\xi d\eta}{k}\,.
\end{aligned}\right\}\quad(3.10)$$

If the functions $g_n(\xi,\eta)$ and $h_n(\xi,\eta)$ are determined such that

$$\left.\begin{aligned}
g_1(\xi,\eta)&=-\frac{t_2 f_1^{(-)}-f_1^{(+)}}{t-1}, \qquad h_1(\xi,\eta)=-\frac{t_1 f_1^{(+)}-f_1^{(-)}}{t-1},\\
g_2(\xi,\eta)&=\frac{t_2 f_1^{(-)}+f_2^{(+)}}{t-1}+\frac{t_2 f_3^{(-)}+f_3^{(+)}}{2(t-1)}+\frac{kd_2 f_3^{(+)}}{t-1}+\left\{\frac{2k(td_1+d_2)}{t-1}-1\right\}\frac{g_3}{2},\\
h_2(\xi,\eta)&=\frac{t_1 f_1^{(+)}+f_2^{(-)}}{t-1}+\frac{t_1 f_3^{(+)}+f_3^{(-)}}{2(t-1)}+\frac{kd_1 f_3^{(-)}}{t-1}+\left\{\frac{2k(td_2+d_1)}{t-1}-1\right\}\frac{h_3}{2},\\
g_3(\xi,\eta)&=\frac{2}{(t-1)^2-4tk^2d^2}\Big\{(t-1)t_2(f_1^{(-)}+f_2^{(-)})+2tkd(f_1^{(+)}+f_2^{(+)})\\
&\qquad+\frac{1}{2}(t-1)(t_2 f_3^{(-)}+f_3^{(+)})+tkd(1+2kd_2)f_3^{(+)}+t_2k(td_1+d_2)f_3^{(-)}\Big\},\\
h_3(\xi,\eta)&=\frac{2}{(t-1)^2-4tk^2d^2}\Big\{(t-1)t_1(f_1^{(+)}+f_2^{(+)})+2tkd(f_1^{(-)}+f_2^{(-)})\\
&\qquad+\frac{1}{2}(t-1)(t_1 f_3^{(+)}+f_3^{(-)})+tkd(1+2kd_1)f_3^{(-)}+t_1k(td_2+d_1)f_3^{(+)}\Big\},
\end{aligned}\right\} \tag{3.11}$$

where $t_1=e^{2kd_1}$, $t_2=e^{2kd_2}$, $t=t_1\cdot t_2=e^{2kd}$, $d=d_1+d_2$, and $f_n^{(-)}$, $f_n^{(+)}$ denote the values of f_n for $z=-d_1$ and $z=d_2$ respectively, the integrals in (3.9) and (3.10) converge and the boundary conditions on the walls (3.4) are satisfied by the sum of (3.9), (3.10) and (3.7). Also, considering (3.11), (u^*, v^*, w^*) and (u^{**}, v^{**}, w^{**}) tend to zero at infinity. Thus, we have a solution satisfying the conditions (3.3) and (3.4) as:

$$\left.\begin{aligned}
u&=u_1+u^*+u^{**}+u_\infty,\\
v&=v_1+v^*+v^{**},\\
w&=w_1+w^*+w^{**},\\
p&=p_1+p^*+p^{**}+p_\infty.
\end{aligned}\right\} \tag{3.12}$$

On the spheroid: $x^2/a^2+(y^2+z^2)/c^2=1$, the flow $(u^*+u^{**}, v^*+v^{**}, w^*+w^{**})$ is expanded in the form:

$$\left.\begin{aligned}
u^*+u^{**}&=\frac{1}{\pi}\iint_{-\infty}^{\infty}\left[(g_1+h_1)+(g_2+h_2)\frac{\xi^2}{k^2}\right]\left(1-\frac{c^2}{2}\eta^2+\cdots\right)\frac{d\xi d\eta}{k}\\
&\quad-\frac{z}{\pi}\iint_{-\infty}^{\infty}\left\{(g_1-h_1)+[(g_2-h_2)-(g_3-h_3)]\frac{\xi^2}{k^2}+\cdots\right\}d\xi d\eta\\
&\quad+\frac{z^2}{\pi}\iint_{-\infty}^{\infty}\left\{\left[(g_1+h_1)+(g_2+h_2)\frac{\xi^2}{k^2}\right]\left(1-\frac{\xi^2}{2k^2}\right)-(g_3+h_3)\frac{\xi^2}{k^2}+\cdots\right\}kd\xi d\eta\\
&\quad-\frac{x^2}{\pi}\iint_{-\infty}^{\infty}\left[(g_1+h_1)+(g_2+h_2)\frac{\xi^2}{k^2}\right]\left(\frac{\xi^2}{k^2}-\frac{c^2}{a^2}\frac{\eta^2}{k^2}+\cdots\right)\frac{k}{2}d\xi d\eta+\cdots,\\
v^*+v^{**}&=-\frac{xy}{\pi}\iint_{-\infty}^{\infty}(g_2+h_2)\left(\frac{\xi^2\eta^2}{k^4}+\cdots\right)kd\xi d\eta+\cdots,\\
w^*+w^{**}&=-\frac{x}{\pi}\iint_{-\infty}^{\infty}\left[(g_1-h_1)+(g_2-h_2)+(g_3-h_3)\right]\left(\frac{\xi^2}{k^2}+\cdots\right)d\xi\, d\eta\\
&\quad+\frac{xz}{\pi}\iint_{-\infty}^{\infty}\left\{\left[(g_1+h_1)+(g_2+h_2)\right]\frac{\xi_2}{k^2}+\cdots\right\}kd\xi d\eta+\cdots.
\end{aligned}\right. \tag{3.13}$$

This (3.13) together with u_∞ tends to the flow mentioned in (2.7). Therefore, using the values of A, B, C, $\cdots$ determined from (2.8), we can also make (3.12) satisfy the conditio (3.5) on the spheroid approximately.

The drag acting on the spheroid and the moment about its centre due to the flow (3.12 are given by (2.10) and (2.11), since those due to the flows except (u_1, v_1, w_1) are all equa to zero.

If, in the $\xi\eta$-plane, we introduce the polar coordinates (k, θ) defined as:

$$\xi = k\cos\theta\,, \quad \eta = k\sin\theta\,,$$

the integration of (3.13) with respect to θ can be carried out directly by expanding th hyperbolic functions. For the last integration, we may rely on numerical means¹⁾.

§ 3.2. Numerical Computations

As a numerical example, we have carried out calculations for the case in which $d_1 = d/$ and $d_2 = 3d/4$, and arrived at the following results:

$$\begin{aligned}
&a_0 = \alpha + 6.9613\,A/d - 9.8466\,a^2A/d^3 - 23.405\,c^2A/d^3 + 0.3594\,B/d^2 - 3.4518\,C/d^2 + \cdots\,,\\
&a_1 = \beta - 9.2766\,A/d^2 + \cdots\,, \qquad\qquad a_2 = \gamma + 33.112\,A/d^3 + \cdots\,,\\
&a_3 = -(29.540 - 20.665\,c^2/a^2)\,A/d^3 + \cdots\,, \qquad b_2 = -8.8748\,A/d^3 + \cdots\,,\\
&c_1 = -11.4340\,A/d^2 + \cdots\,, \qquad\qquad c_2 = 67.955\,A/d^3 + \cdots\,. \qquad (3.14
\end{aligned}$$

Substituting these values into (2.8), we have

$$\left.\begin{aligned}
&A\left\{1 - \frac{1}{l(K+a^2L_1)}\left(1.7403 - 0.3077\,\frac{a^2}{l^2} - 0.0856\,\frac{c^2}{l^2}\right)\right\}\\
&\quad = \frac{1}{K+a^2L_1}\left\{\left(\alpha + \frac{c^2}{3}\gamma\right) + 0.0225\,\frac{B}{l^2} - 0.2157\,\frac{C}{l^2}\right\}\,,\\
&B = \frac{2c^2}{l(K+a^2L_1)}\left\{l\beta - \left(0.5798 - 0.7146\,\frac{a^2}{c^2}\right)\frac{A}{l}\right\}\,,\\
&C = \frac{2}{l(K+a^2L_1)}\,\frac{L_1}{M_3}\left\{l\beta - \left(0.5798 + 0.7146\,\frac{L_3}{L_1}\right)\frac{A}{l}\right\}\,,\\
&\quad\cdots\cdots\cdots\cdots\,,
\end{aligned}\right\} \quad (3.15$$

where l denotes the distance from the centre of the spheroid to the nearer wall, i.e. $l = d/4$ and the relation: $a^2L_1 + c^2L_3 = (K + a^2L_1)/2$ has been used. G becomes zero in the case of sphere.

By (3.15), the effect of the boundary walls can be estimated for A up to the order o $(a \text{ (or } c)/l)^4$ and for B up to the order of $(a \text{ (or } c)/l)^3$.

Using the values of A and B determind from (3.15), we can obtain the formulae for th drag and the moment in three cases such as:

Case (A) in which a spheroid is moving with a constant velocity $(-U)$ along the x-axis

Case (B) in which a spheroid is in the Couette flow which may be realized by the stead translstion of one of the two walls in its own plane,

Case (C) in which a fixed spheroid is immersed in the two-dimensional Poiseuille flow, which correspond respectively to three sets of the values of (α, β, γ) in (3.2), namel $(U, 0, 0)$, $(U, U/d_1, 0)$ and $(U, 2U/d_2, -U/(d_1d_2))$. Some values of $W\Big/\dfrac{16\pi\mu U}{K+a^2L_1}$ and $N/\mu c^2U$ are shown in Tables I and II.

It can be seen from (3.15) that the moment due to the additional flow $(u^* + u^{**}, v^* + v^{**}, w^* + w^{**})$ changes its sign when the ratio a/c exceeds a certain definite value. If terms o the order higher than $(a \text{ (or } c)/l)^3$ are neglected, we have

$$(a/c)_{\text{crit}} \doteqdot 0.901 \qquad (3.16$$

Table I. Values of $W\Big/\dfrac{16\pi\mu U}{K+a^2L_1}$

Case (A) in which $u_\infty=U$:

c/l \ a/c	0	0.5	1	2	4
0.05	1.03	1.03	1.03	1.04	1.05
0.1	1.06	1.06	1.07	1.08	1.11
0.2	1.12	1.13	1.15	1.18	1.23

0.3	8.98	9.75	11.51	18.8	

Case (C) in which $u_\infty=U(1+z/d_1)(1-z/d_2)$:

c/l \ a/c	0	0.5	1	2	4
0.01	0.21	0.23	0.25	0.31	0.44
0.05	1.05	1.13	1.26	1.63	3.04
0.1	2.07	2.23	2.53	3.53	8.34
0.2	4.00	4.43	5.11	8.22	27.0
0.3	5.78	6.33	7.74	14.3	

as the critical value at which such an effect just vanishes (cf. Fig. 1).

In particular, the formulae of the drag and the moment for a circular plate perpendicular both to the main stream and to the walls are expressed as follows:

Case (A) in which $u_\infty=U$,

$$W=16\,\mu cU\,/\,(1-0.5540\,c/l+0.0272\,c^3/l^3-0.023\,c^4/l^4)\ ,$$

$$N=-32\,\mu c^2U(c/l)(0.1846\,c/l+0.102\,c^2/l^2)\ .$$

Case (B) in which $u_\infty=U(1+z/l)$,

$$W=16\,\mu cU\,/\,(1-0.5540\,c/l+0.1502\,c^3/l^3-0.023\,c^4/l^4)\ ,$$

$$N=32\,\mu c^2U(c/l)(1-0.1846\,c/l-0.102\,c^2/l^2)\ .$$

Case (C) in which $u_\infty=U(1+z/l)(1-z/3l)$,

$$W=16\,\mu cU(1-c^2/9l^2)\,/\,(1-0.5540\,c/l+0.1092\,c^3/l^3-0.023\,c^4/l^4)\ ,$$

$$N=\frac{16}{3}\,\mu c^2U\,(c/l)(1-0.2769\,c/l-0.153\,c^2/l^2)\ .$$

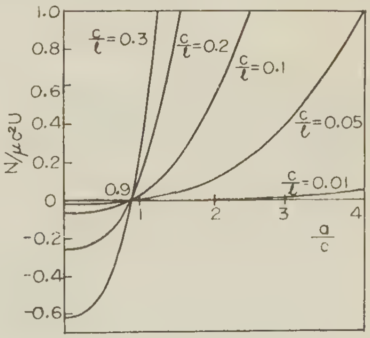

Fig. 1. $N/\mu c^2U$ in the case (A).

On the other hand, the formulae for W and N in the case of a sphere become respectively

Case (A):—

$$W=6\pi\mu aU/(1-0.6526\,a/l+0.1475\,a^3/l^3-0.132\,a^4/l^4)\,,$$
$$N=12\pi\mu a^2U(a/l)(0.0506\,a/l+0.033\,a^2/l^2)\,.$$

Case (B):—

$$W=6\pi\mu aU/(1-0.6526\,a/l+0.4003\,a^3/l^3-0.132\,a^4/l^4)\,,$$
$$N=12\pi\mu a^2U(a/l)(1+0.0506\,a/l+0.033\,a^2/l^2)\,.$$

Case (C):—

$$W=6\pi\mu aU(1-a^2/9l^2)/(1-0.6526\,a/l+0.3160\,a^3/l^3-0.132\,a^4/l^4)\,,$$
$$N=8\pi\mu a^2U(a/l)(1+0.0758\,a/l+0.049\,a^2/l^2)\,.$$

Some of these formulae for a sphere have already been obtained[1),3)] correct to the order of $(a/l)^5$.

FLOWS PAST A SPHEROID IN A CYLINDRICAL PIPE

§ 4.1. General Formulae

Next, utilizing the solution (2.6), we shall consider the flow past a spheroid in an infinitely long straight pipe having a circular cross section, its axis coinciding with the axis of symmetry of the spheroid, i.e. the x-axis.

We assume that the undisturbed flow through the pipe has the form:

$$u_\infty=\alpha+\delta(y^2+z^2)\,,\qquad v_\infty=w_\infty=0\quad(\alpha,\ \delta\text{: constants})\tag{4.1}$$

which together with

$$p_\infty=4\mu\delta x+\text{const.}$$

satisfies (2.1) and (2.2). Then the boundary conditions to be satisfied are

$$u=u_\infty\,,\quad v=w=0\qquad\text{for}\quad x=\pm\infty\,,\tag{4.2}$$
$$u=v=w=0\qquad\text{for}\quad \sqrt{y^2+z^2}=r_0\,,\tag{4.3}$$
$$u=v=w=0\qquad\text{on the spheroid}\,,\tag{4.4}$$

where r_0 is the radius of the pipe.

Integrating (2.12) or (2.12a) with respect to η and ζ, we find that, when $r\ (=\sqrt{y^2+z^2})>|\varepsilon|$,

$$\left.\begin{aligned}\chi_0&=\frac{4}{\pi}\int_0^\infty\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}K_0(\xi r)\cos(\xi x)d\xi\,,\\ x\chi_0&=\frac{4}{\pi}\int_0^\infty\left.\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}\xi rK_1(\xi r)-\left[\cosh(\varepsilon\xi)-\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi}\right]K_0(\xi r)\right\}\sin(\xi x)\frac{d\xi}{\xi}\,,\\ \chi_1&=-\frac{4}{\pi}\int_0^\infty\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2}-\frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right]K_0(\xi r)\cos(\xi x)d\xi\,,\end{aligned}\right\}\tag{4.5}$$

where K_n is the modified Bessel function of the second kind.

In the present case, due to the symmetry of the field we may put

$$B=C=D=E=0\,.$$

Then, using (4.5), general solution (2.6) is expressed for $r>|\varepsilon|$ in the integral forms as:

$$\left.\begin{aligned} u_1 &= \frac{4}{\pi}\int_0^\infty \Big\{ S_1\xi r K_1(\xi r) - (2S_1+T_1)\,K_0(\xi r) \Big\} \cos(\xi x)d\xi\;, \\ q_1 &= \frac{y}{r}\,v_1 + \frac{z}{r}\,w_1 = \frac{4}{\pi}\int_0^\infty \Big\{ T_1 K_1(\xi r) - S_1\xi r K_0(\xi r) \Big\} \sin(\xi x)d\xi\;, \\ p_1 &= -\mu\frac{8}{\pi}\int_0^\infty S_1\xi K_0(\xi r)\sin(\xi x)d\xi\;, \end{aligned}\right\} \tag{4.6}$$

referring to the cylindrical coordinates $(x,\ r,\ \varphi)$, where

$$S_1(\xi) = A\frac{\sinh(\varepsilon\xi)}{\varepsilon\xi} + \cdots, \qquad T_1(\xi) = Ac^2\xi^2\left[\frac{\cosh(\varepsilon\xi)}{(\varepsilon\xi)^2} - \frac{\sinh(\varepsilon\xi)}{(\varepsilon\xi)^3}\right] + \cdots. \tag{4.7}$$

Hence, the second solution may be found as follows:

$$\left.\begin{aligned} u_2 &= \frac{4}{\pi}\int_0^\infty \Big\{ S_2\xi r I_1(\xi r) + (2S_2+T_2)I_0(\xi r) \Big\} \cos(\xi x)d\xi\;, \\ q_2 &= \frac{4}{\pi}\int_0^\infty \Big\{ T_2 I_1(\xi r) + S_2\xi r I_0(\xi r)d\xi \Big\} \sin(\xi x)d\xi\;, \\ p_2 &= \mu\frac{8}{\pi}\int_0^\infty S_2\xi I_0(\xi r)\sin(\xi x)\,d\xi\;, \end{aligned}\right\} \tag{4.8}$$

where I_n is the modified Bessel function of the first kind.

If the functions $S_2(\xi)$ and $T_2(\xi)$ are determined such that

$$\left.\begin{aligned} S_2(\xi) &= S_1(\xi)\frac{K_0(\xi r_0)}{I_0(\xi r_0)} - \frac{1}{\Delta}\left\{ S_1(\xi)\frac{I_1(\xi r_0)}{I_0(\xi r_0)} - \frac{T_1(\xi)}{\xi r_0} \right\}, \\ T_2(\xi) &= T_1(\xi)\frac{K_0(\xi r_0)}{I_0(\xi r_0)} - \frac{1}{\Delta}\left\{ T_1(\xi)\left(\frac{I_1(\xi r_0)}{I_0(\xi r_0)} + \frac{2}{\xi r_0}\right) - S_1(\xi)\xi r_0 \right\}, \end{aligned}\right\} \tag{4.9}$$

with

$$\Delta = 2I_0(\xi r_0)I_1(\xi r_0) - \xi r_0\{[I_0(\xi r_0)]^2 - [I_1(\xi r_0)]^2\}\;,$$

the integrals in (4.8) converge and the boundary conditions on the inner surface of the pipe are satisfied by (4.6) and (4.8). Also, with the value of (4.9), $u_2 = q_2 = 0$ for $x = \mp\infty$ and p_2 at infinity is evaluated as:

$$(p_2)_{x=\mp\infty} = \mp 4\mu[S_2(\xi)\xi^2 I_0(\xi r)]_{\xi=0}\;, \tag{4.10}$$

by applying Dirichlet's integral theorem.

The flow $(u_2,\ q_2)$ is expanded on the spheroid in approximately the same form as (2.7) where $a_1 = a_2 = c_1 = 0$ and $b_2 = c_2$, namely:

$$\left.\begin{aligned} u_2 &= \frac{4}{\pi}\int_0^\infty \Big\{ (2S_2+T_2) + (S_2+T_2/4)c^2\xi^2 + \cdots\cdot \Big\} d\xi \\ &\quad - x^2\frac{4}{\pi}\int_0^\infty \Big\{ [(2S_2+T_2)/2 + (c^2/a^2)(S_2+T_2/4)]\,\xi^2 + \cdots \Big\} d\xi + \cdots\;, \\ q_2 &= xr\frac{4}{\pi}\int_0^\infty \Big\{ (2S_2+T_2)\xi^2/2 + \cdots \Big\} d\xi + \cdots\;. \end{aligned}\right\} \tag{4.11}$$

On the spheroid, the undisturbed flow (4.1) becomes

$$u_\infty = (\alpha + c^2\delta) - (c^2/a^2)\delta x^2\;, \qquad v_\infty = w_\infty = 0\;, \tag{4.12}$$

which may also be regarded as a special case of the flows of type (2.7).

Thus, we can obtain the approximate solution of the problem as follows:

$$\left.\begin{aligned}&u=u_1+u_2+u_\infty\,,\\&q=(y/r)v+(z/r)w=q_1+q_2\,,\\&p=p_1+p_2+p_\infty\,.\end{aligned}\right\}\tag{4.13}$$

Our solution (4.13) satisfies exactly the boundary conditions on the walls as well as at infinity, and also satisfies the ones on the surface of the spheroid approximately with the values of A, B, C, $\cdots$ as determined by (2.8).

The integrals in (4.11) may be evaluated numerically. We have thus obtained, from (4.11) and (4.12),

$$\left.\begin{aligned}&a_1=\alpha+c^2\delta+(5.6112-1.0106\,a^2/r^2_0-4.4289\,c^2/r_0^2)A/r_0+\cdots\,,\\&a_3=-(c^2/a^2)\delta-(3.0316-2.6574\,c^2/a^2)A/r_0^3+\cdots\,,\\&b_2=c_2=3.0316\,A/r_0^3+\cdots\,.\end{aligned}\right\}\tag{4.14}$$

By inserting these values into (2.8), we have, neglecting the terms of the order higher than $(a \text{ (or } c)/l)^4$,

$$A=\frac{1}{K+a^2L_1}\left(\alpha+\frac{2}{3}c^2\delta\right)\Bigg/\left\{1-\frac{1}{r_0(K+a^2L_1)}\left(5.6112-2.0211\frac{a^2}{r_0^2}-3.5431\frac{c^2}{r_0^2}\right)\right\}\,. \tag{4.15}$$

§ 4.2. Drag and Blocking Effect of the Spheroid

When the constants $(\alpha,\ \delta)$ involved in u_∞ take the values $(U,\ 0)$ or $(U,\ -U/r_0^2)$, we have either of the following two cases respectively:

Case (A) in which a spheroid is moving with constant velocity $(-U)$ along the axis of the pipe.

Case (B) in which a fixed spheroid is immersed in the Poiseuille flow through the pipe.

The additional pressure difference between the both ends of the pipe which is required to maintain the same total flux through the pipe as in the case of no spheroid is given by

$$\varDelta p=2(p_2)_{x\to-\infty}=32\,\mu\frac{A}{r_0^2}\left(1-\frac{2}{3}\frac{c^2}{r_0^2}\right)+\cdots\,. \tag{4.16}$$

On the other hand, the drag acting on the spheroid due to the flow (4.13) is given by (2.10) as well. Hence, as far as terms of the order higher than $(a \text{ (or } c)/l)^3$ are neglected, the force P necessary for maintaining the pressure difference as given by (4.16) is connected with the drag of the spheroid by the relation:

$$P=\varDelta p\,\pi r_0^2=2W\left(1-\frac{2}{3}\frac{c^2}{r_0^2}\right), \tag{4.17}$$

which should be compared with the case of the sphere problem[5)].

In particular, the formulae for W and $\varDelta p$ for a circular plate $(a=0)$ are given as follows:

$$W=16\,\mu c\left(\alpha+\frac{2}{3}c^2\delta\right)\Bigg/\left(1-1.786\frac{c}{r_0}+1.128\frac{c^3}{r_0^3}\right), \tag{4.18}$$

$$\varDelta p=\frac{32\,\mu c}{\mu r_0^2}\left\{\alpha+\frac{2}{3}c^2\left(\delta-\frac{\alpha}{r_0^2}\right)\right\}\Bigg/\left(1-1.786\frac{c}{r_0}+1.128\frac{c^3}{r_0^3}\right), \tag{4.19}$$

where $\alpha=U$, $\delta=0$ in the case (A) and $\alpha=U$, $\delta=-U/r_0^2$ in the case (B).

The results for the case of the sphere are in perfect agreement, to our present approximation, with those obtained previously by the present author[2)], namely

$$W=6\,\pi\mu a\left(\alpha+\frac{2}{3}a^2\,\delta\right)\Bigg/\left(1-2.104\frac{a}{r_0}+2.087\frac{a^3}{r_0^3}\right),$$

and so on.

The values of $W\Big/\dfrac{16\pi\mu U}{K+a^2L_1}$ and $P\Big/\dfrac{32\pi\mu U}{K+a^2L_1}$ or some values of a/c and c/l are shown in ables III∼V.

Table III. Values of $W\Big/\dfrac{16\pi\mu U}{K+a^2L_1}$ for $u_\infty=U$.

Structure of Magnesium Fluoride Films on Amorphous Substrates

By Nobuyoshi MORITA

Scientific Research Institute, Tokyo

(Received April 6, 1957)

Structure of magnesium fluoride films of thickness from 40 Å to 8000 Å evaporated on optical glass and on fused quartz was studied by means of electron microscope and diffraction and its correlation with optical properties and tenacity of the films was examined. Films deposited at room temperature are amorphous, and the grains remain considerably small and tend to grow in height. Effects of residual gas, contamination of substrate surface and rate of deposition were examined. Films deposited in poor vacuum are shown to be porous in structure. Films deposited on substrate kept above 220°C have [301] preferred orientation, and the grains remain thin and grow along the substrate surface. The causes of tenacity of the films deposited at high substrate temperatures are discussed.

§ 1. Introduction

Properties of evaporated magnesium fluoride films depend upon the conditions of preparation. For example, scattering of light from films depends upon substrate material and substrate temperature during deposition.[1] Refractive index depends upon the conditions of evaporation as seen by reported values ranging between 1.35 and 1.41.[1][2][3] Structure of metal films has hitherto been studied extensively by electron microscope,[4][5] but little attention has been given to structure of magnesium fluoride films in spite of the fact that they are widely used in optics. In the previous paper,[1] the film structure was inferred based upon the experimental results about optical properties of magnesium fluoride films. It is the purpose of the present investigation to examine the effects of condition of preparation on the structure by means of electron microscope and diffraction, particularly the effects on the structure due to (1) material and temperature of substrate, (2) film-thickness, (3) deposition rate and pressure of residual gas and to correlate the observed structure with optical properties and tenacity of the films.

§ 2. Experimental Procedures

Magnesium fluoride was evaporated from tungsten basket onto borosilicate crown glass (BK7) or fused quartz placed 22 cm above the basket. To degas adsorbed molecules, the substrate was heated at 350°C for an hour high vacuum before deposition. Film w deposited at the rate between 200 Å/min an 300 Å/min at pressure 5×10^{-5} mmHg. Th measurement of film-thickness was carrie out by multiple-beam interferometry.[6] Th surface structure of film was studied by a electron microscope* using carbon replica.

§ 3. Experimental Results

(1) Change in structure with increasin film-thickness

Films of thickness from 40 Å to 8000 Å we examined. Some of them were deposite simultaneously on an optical glass and a fuse quartz plate in order to study the effect substrate on the film structure. When a fil is deposited on fused quartz at room tempe ature (Fig. 1), it consists of patches of i regular shape at 40 Å thickness. With i creasing thickness, the initially develope patches do not increase in size but interstic between them are filled and the surface film becomes extremely smooth at 280 Å thic ness. With further increase of film-thicknes the grain size increases gradually and becom as large as 300 Å in films of thickness 5000 When a film is deposited on fused quartz 400°C (Fig. 2), the grains are aggregated in nearly spherical granules at 40 Å thicknes With increasing thickness, the grains join ar merge together in large and flat grains.

room temperature, no remarkable difference due to substrate material is detected. At higher temperatures, difference in film structure is distinct. Films on fused quartz show granular surface and those on optical glass show considerably flat appearance (Figs. 2(c) and 3). Moreover, in films of thickness above 6000 Å on fused quartz many cracks are observed which separate the film into blocks of about 10 μ (Fig. 4), while films deposited simultaneously on optical glass show no such cracks. The scattering of light by films on fused quartz which has been reported by the present author1) is found to be caused by the cracks in the film.

(2) Effects of substrate temperature on structure and tenacity of films

The surface structure of films deposited at high temperatures is distinctly different from that deposited at room temperature (Figs. 1 and 2). It is well known that films deposited at high temperatures adhere to glass surface with greater tenacity than those deposited at room temperature.7) In order to find out correlation between tenacity and structure of films, films of thickness about 700 Å were deposited at various temperatures from 30°C to 400°C and both tenacity and structure of the films were examined. Tenacity of film was measured with abrasion test. Film surface was rub-

bed with a piece of glass with spherical surface (radius of curvature 10 mm) which was pressed against the film surface under a given weight. With each weight, the surface was rubbed several times at different places. The heaviest weight which the film could withstand and the lightest with which the film was injured on the average were determined. The value of tenacity of the film was defined to lie within these two values. Tenacity of film increases rapidly as substrate temperature is raised (Fig. 5). The difference in tenacity due to substrate material can scarcely be detected. Films deposited on optical glass at 90°C (Fig. 6(b)) consist of extremely fine grains which are far smaller than those of films deposited at 30°C (Fig. 6(a)). The grains in films deposited at 230°C (Fig. 6(c)) are nearly of the same size as those of films deposited at 30°C but show the tendency to remain thin and to grow along the substrate surface, while the grains in films deposited at 30°C show the tendency to grow more in height, i.e. become thicker before joining together. Heat treatment at 350°C for an hour in vacuum after deposition was found to reduce height of grains in films deposited at room temperature. The effect on flattening of the film surface by heat treatment, however, is smaller than that by depositing at 230°C. The tenacity of films which underwent heat treatment after deposition is between those of films deposited at room temperature and 230°C.

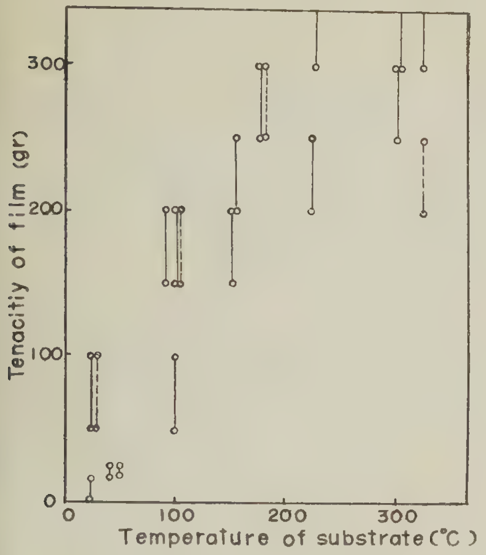

Fig. 5. Experimental value of tenacity of film 700 Å thick as a function of substrate temperature. Full line indicates the value for film depositted on optical glass and dotted line indicates the value for film deposited on fused quartz.

(3) Effect of residual gas on structure of films deposited at room temperature

Films of thickness about 500 Å were deposited on fused quartz at room temperature at various pressures from 5×10^{-5} mmHg to 7×10^{-4} mmHg. Films deposited in poor vacuum (Fig. 7) have more aggregated structure than those deposited in high vacuum.

(4) Effect of contamination of substrate surface on structure of films deposited at room temperature

A fused quartz plate was cleaned by clothes dipped in the mixture of ethyl alcohol and ether and was used as substrate without degasing it in vacuum before deposition. The film of thickness 200 Å deposited on such a substrate (Fig. 8) is more granular than the film of nearly the same thickness deposited on a degased substrate surface (Fig. 1(b)).

(5) Effect of evaporation rate on structure of films deposited at room temperature

Two films of thickness about 600 Å were prepared, one taking 1 minute for deposition and the other 15 minutes. The slowly deposited film has more aggregated structure and larger surface area than the rapidly deposited film (Figs. 9(a) and 9(b)).

(6) Results of electron diffraction study

Electron diffraction by reflection failed to give any distinct pattern for films deposited on optical glass at room temperature. By films of thickness 7000 Å deposited on fused quartz at room temperature, a faint pattern which is likely to indicate [301] orientation can be obtained, though no such patterns are observed for films deposited simultaneously on optical glass.

At substrate temperatures above 220°C, however, [301] orientation can be observed at thickness below 1000 Å (Fig. 10). This reflection continues to dominate the pattern as the film thickness is increased up to 6000 Å. This orientation can also be detected in thin films below 1000 Å deposited at 220°C at high pressures such as 5×10^{-3} mmHg, though diffuseness of the pattern is larger for such films. No remarkable difference in the pattern due to substrate material is detected at high temperatures.

§ 4. Discussion of the Results

(1) Crystallization in films

The growth of magnesium fluoride films deposited at room temperature does not follow the usual sequence which can be seen in metal films such as silver⁵⁾ and gold.⁸⁾ According to Schulz,⁹⁾ films up to thickness 1000Å deposited on slide glass at room temperature produce no reflection pattern, but films of thickness from 2000 Å to 1 μ, a faint broad rings with (301) reflection. In the present experiment, (301) reflection is observed only for films deposited on fused quartz but not on optical glass at room temperature. Grains of size about 300 Å observed in films of thickness 5000 Å (Fig. 1(c)) might not be individual crystallites, for crystallites of this size would have given sharp rings. At room temperature, the kinetic energy of deposited molecules is insufficient to surmount the potential barrier on substrate surface, and crystallization can not develop in the film on account of extremely limited range of migration of the deposited molecules on the substrate surface. At high substrate temperatures, the deposited molecules on substrate surface obtain sufficient energy to surmount the barrier on the surface and crystallize rapidly. The [301] orientation observed in films deposited at high temperatures originates from the tendency of molecules to aggregate first in close packing to form plane sheets of monomolecular thickness on the substrate, as (301) plane is the most densely populated net plane in magnesium fluoride crystal. Though the films deposited at 30°C and at 230°C have similar appearance of surface as shown in Figs. 6(a) and 6(c), respectively, the former is amorphous and the latter is crystalline having distinct orientation.

(2) Coagulation in films due to adsorbed gas molecules

High pressure of residual gas, contamination of substrate surface and slow rate of evaporation are all effective in increasing grain size in thin films deposited at room temperature. As these films are amorphous, grains in the films are formed merely by coagulation and not by crystal growth. These effects seem to be caused mainly by gas molecules adsorbed on substrate and film surface. At pressure 5×10^{-5} mmHg, the rate at which residual gas molecules strike a surface is such as to form five molecular layers in a second. The assumption that some of these residual gas molecules are adsorbed on substrate and film surface kept at room temperature and coagulate the grains in the film will be confirmed from comparison of Fig. 6(a) with Fig. 6(b). As the residual gas molecules impinged upon the surface kept at 90°C would reevaporate from the surface, the deposited magnesium fluoride molecules stick to the place where they hit the substrate under the strong binding force of the substrate. Accordingly, grains in the film remain extremely small without coagulating together. At room temperature, however, adsorbed layers prevent the deposited molecules from coming within the true surface force of the substrate and reduce the binding force of substrate to the deposits. Therefore, the deposited molecules can not stick to the place where they hit the substrate, but coagulate together to form large grains in the film apart from the substrate surface. The flat surface of films deposited at high temperatures compared with that of films deposited at room temperature (Fig. 6(c) and Fig. 6(a) or Fig. 2 and Fig. 1) suggests the reduced effect of residual gas on coagulation of the deposits and the development of crystallization in the films. Such films can be thought to be compact and stable in structure. The fact that films which underwent heat treatment have also flattened surface suggests that residual gas molecules occluded in the films are released from the films and crystallization is stimulated both by removal of the residual gas and increased kinetic energy of the deposited molecules.

The coagulation in films deposited at slow rate of evaporation is not so distinguished as that observed in metal films such as antimony[4] and silver.[5] As the range of migration of magnesium fluoride molecules is extremely small compared with that of the metal atoms, the effect of evaporation rate on the mobility of deposited molecules may be considerably small. Therefore, residual gas molecules adsorbed on the film surface during prolonged deposition would be the main cause for coagulation of the slowly deposited films.

In poor vacuum, residual gas affects the molecular beam by producing collisions between the individual evaporated molecules near the filament, producing thereby large clumps of molecules before they reach the substrate. The film deposited at pressure 7×10^{-4} mmHg* (Fig. 7) is thought to be formed by deposition of these large clumps of molecules and porous in structure having voids within the film.

(3) Correlation between structure and optical properties of films

As films deposited at room temperature in poor vacuum are porous in strucure (Fig. 7), the films can be thought to have lower refractive index than the bulk material from Lorentz-Lorenz formula which relates the refractive index with the density. The variations in refractive indices which are lower than the bulk material[10][11] as reported by some investigators[2][3] for the films deposited at room temperature, can be explained by the different amount of voids in the films. The aging effect observed for such films[2][3] is thought to be caused by sintering of coagulated grains in the porous films with time.

* The mean free path of magnesium fluoride molecules at this pressure is 3 cm.

As the coagulation of grains due to adsorbed gas molecules is observed in films deposited at room temperature at pressure 5×10^{-5}mmHg (Fig. 6(a)), such films may also be considered to be porous in structure and sinter with time. As reported in the previous paper, however, their refractive indices are the same as that of the bulk material within the experimental error of 1 %, and the contractions in film-thickness shown by some of them are only several milli-microns. Therefore, it can not be concluded decidedly that such films are porous and sinter with time. The fact that films deposited at high temperatures show no contraction as reported in the previous paper, indicates the stable structure of the films in accordance with the conclusion obtained by the present experiment.

The fact that grains in films deposited at room temperature remain sufficiently small compared with the wavelength of visible light and those deposited on optical glass at high temperatures remain thin and grow along the substrate surface explains the small scattering of light from such films.[1)]

(4) Correlation between structure and tenacity of films

Tyler[7)] has suggested that the increase in durability and tenacity of magnesium fluoride films might be caused by high concentration of high energy magnesium fluoride molecules. The author[12)] examined the tenacity of cryolite films prepared under various conditions and pointed out that it is essential for obtaining tenacious films to prevent residual gas molecules from depositing within the films. It was found by the present experiment that coagulation of grains in height caused by adsorbed gas molecules has tendency to reduce the tenacity of the films when deposited at room temperature. On the contrary, tenacious films which may be thought to scarcely be affected by gas molecules were found to consist of extremely fine grains. Films deposited at high substrate temperatures also have flat appearance of surface and are extremely tenacious. Accordingly, smoothness of film surface is thought to be a factor which favour the tenacity of the films. The great hardness of films obtained at high deposition temperatures indicates the strong cohesive force within the films and large adhesive force of deposited molecules to the substrate. The fact that films obtained at high deposition temperatures have definite crystal orientation and little tendency to grow in height suggests the compact structure of films and strong cohesive force within the films. The strong adhesive force may be caused by the increased binding force of oxygen atoms of substrate at high temperatures to deposited magnesium fluoride molecules.

(5) Difference in affinity of optical glass and fused quartz to magnesium fluoride molecules

The different behavior of films deposited simultaneously on optical glass and fused quartz as is explained in § 3 (1) and (6), suggests that surface force of optical glass to the deposited magnesium fluoride molecules is larger than that of fused quartz. Optical glass used as substrate contains sodium and potassium ions which are thought loosely bound by surrounding oxygen atoms.[13)] Strong surface force of glass substrate to the deposited magnesium fluoride molecules may be attributed to these ions in the glass.

Summary

Thin films of magnesium fluoride when deposited on optical glass and on fused quartz kept at room temperature consist of extremely fine grains. Distinct reflection patterns can not be obtained for such films by electron diffraction. High pressure of residual gas, surface contamination and slow rate of deposition stimulate the coagulation of grains in height.

The possibility of lower refractive index and sintering with time can be considered for films which are affected by the residual gas molecules.

In films deposited at high substrate temperatures, [301] preferred orientation is found to be distinct. With increasing film-thickness, the grains aggregste rapidly to form large and flat granules.

Scattering of light by films deposited on fused quartz kept at high temperatures is found to be caused by cracks in the films.

The tenacity of films has close correlation with flatness of film surface, compactness of films and surface force of substrate atoms to the deposited magnesium fluoride molecules.

The author is deeply indebted to Miss E. Iguchi of Akashi Manufacturing Co., Ltd. for the preparation of electron micrographs and to Dr. S. Yamaguchi for electron diffraction observation. He expresses his sincere thanks to Professor R. Uyeda for stimulating the investigation by electon microscope with carbon replica and for comments on the manuscript prior to publication, to Professor K. Ishiguro for advices on preparing the paper and to Dr. K. Shinohara for his continued encouragement and guidance.

The Visco-elastic Properties of Network Structure

II. Structural Viscosity

By Misazo YAMAMOTO

Department of Chemistry, Faculty of Science, Kyoto University

(Received July 1, 1957)

Viscosity behaviors of concentrated polymer solution are treated by making use of the model of weak Gaussian network. If chain-breakage coefficient, i.e. the probability of breakage of a chain in the network is independent of elongation of the chain, such system shows the Newtonian flow. Proper choice of chain-breakage coefficient, for example, that of square well type, yields a typical rate dependence of viscosity; the larger the rate of shearing flow, λ, the smaller the value of viscosity coefficient, μ. The tensile viscosity, μ^*, is also considered, which in general increases with the rate of stretching, λ^*, for small values of the rate. The so-called Trouton's formula, $\mu^*=3\mu$ is satisfied only in the limit of zero values of rates λ and λ^*.

§ 1. Introduction

The so-called structural viscosity or, in modern terminology, non-Newtonian viscosity is one of the most interesting rheological phenomena on high polymeric systems. In solutions of high polymeric substances, usually the viscosity is very sensitive to rate of shear of the flow; the larger the rate of shear, the smaller the value of viscosity coefficient. It is likely that in such systems there exists some structure which may respond to this particular behavior. When the magnitude of applied deformation or its time rat becomes larger, such structure may progressively be broken down and, as a result the resistance of the system to the deformatio becomes smaller. For extremely dilute solutions of polymers where interactions betwee coiled chain molecules are negligible, a numbe of theoretical studies have been worked ou on their rheological behavior by previous investigators.[1] It appears, however, that n satisfactory theory is yet available for the structural viscosity of concentrated polymer solution.

When the concentration of a given polymer solution is increased, the viscosity coefficient increases rapidly and its shear-rate dependence becomes quite marked. In such solutions the interchain interactions may play a role in their rheological behavior. The chain molecules may entangle each other and form a temporary, weak network structure throughout the solution. In a previous paper[2)] a statistical mechanical theory of such a weak network structure was presented and in terms of it the stress-strain relation for general deformation was derived. One of the purposes of the present paper is to provide the concrete expression of the shearing stress for simple shear deformation. It is shown that, when the probability at which the network "junction" breaks is independent of the state of network deformation, the shearing stress becomes proportional to the rate of shear. This results in the viscosity coefficient, μ, independent of rate of shear. This is actually the particular case investigated by Green and Tobolsky,[3)] and is nothing but an ideal case. In actual systems the probability of chain breakage may increase with increasing tension acting on network junctions. It is shown below that such a system really shows a typical structural viscosity.

The so-called tensile viscosity, μ^*, is also considered for simple elongation. The classical theory of elasticity shows a simple relation to hold between the viscosity coefficients for shearing and stretching deformations, that is

$$\mu^* = 3\mu \tag{1}$$

This relation is sometimes called Trouton's formula. For actual polymeric substances, this in general does not obtain. Nitchmann-Schrade's experimental results[4)] for concentrated solutions of nitrocellulose in diphenyl chloride show that the tensile viscosity coefficient increases with rate of stretching. This behavior should be contrasted with that in simple shearing. It is shown that our network theory yields a qualitative interpretation of these characteristics of viscosity behavior as functions of rate of deformation.

§ 2. General Considerations

From the statistical thermodynamical point of view, viscous flow is considered as one of the dissipative processes. In terms of the energy of dissipation $\Delta\mathcal{E}$ in a simple shearing flow the viscosity coefficient μ is defined by the equation

$$\mu = \Delta\mathcal{E}/\lambda^2 , \tag{2}$$

where λ is the rate of shear or the velocity gradient of the flow. The viscosity coefficient is usually defined in terms of the shearing flow. However, it is possible to extend the concept of viscosity to deformations of other types, if rates of deformation are properly defined in respective cases. For example, let us consider simple elongation. It is shown that the length α^* of the sample must be changed exponentially with time to maintain the deformation steady. Thus

$$\alpha^* = \alpha_0^* e^{\lambda^* t} , \tag{3}$$

where λ^* is considered as a measure for the rate of stretching. We may then apply Eq. (2) and define the "tensile viscosity" or "Trouton viscosity" coefficient μ^*. In terms not of energy of dissipation but of normal stress σ^* and strain α^*, μ^* is then defined such that

$$\mu^* = \sigma^* \Big/ \frac{1}{\alpha^*}\frac{d\alpha^*}{dt} = \sigma^*/\lambda^* . \tag{4}$$

In this paper, for simplicity of calculation, we assume that any chain in polymer network is represented by the Gaussian chain, i.e., its free energy, ϕ, for stretching is proportional to the square of the end-to-end distance $\boldsymbol{h} = (\xi, \eta, \zeta)$, such that

$$\phi(|\boldsymbol{h}|, N, T) = \frac{3kT}{2}\frac{|\boldsymbol{h}|^2}{a^2 N} , \tag{5}$$

where k is Boltzmann constant, T is the absolute temperature, and a and N are the length and the number of statistical segments in a chain, respectively. It has been shown in a previous paper that with this simplification, the stress tensor $\boldsymbol{s}$ corresponding to the strain tensor $\boldsymbol{e}$ is given in terms of the "chain distribution function" $F(\boldsymbol{h}, N, t)$. Thus

$$\boldsymbol{s} = \boldsymbol{s}_n + P\boldsymbol{1} \tag{6}$$

with

$$\boldsymbol{s}_n = \sum_N \iiint \frac{3kT}{a^2 N} (\boldsymbol{hh}) F(\boldsymbol{h}, N, t) d\boldsymbol{h} , \tag{7}$$

where $(\boldsymbol{hh})$ is a tensor defined as

$$(\boldsymbol{hh})=\begin{pmatrix} \xi^2 & \xi\eta & \xi\zeta \\ \eta\xi & \eta^2 & \eta\zeta \\ \zeta\xi & \zeta\eta & \zeta^2 \end{pmatrix}. \qquad (8)$$

It has been shown[2)] that the chain distribution function F must satisfy

$$\frac{\partial F(\boldsymbol{h}, N, t)}{\partial t} = -\nabla F(\boldsymbol{h}, N, t)\frac{d\boldsymbol{e}}{dt}\boldsymbol{e}^{-1}\boldsymbol{h} - \frac{1}{|\boldsymbol{e}|}\frac{d|\boldsymbol{e}|}{dt}F(\boldsymbol{h}, N, t)+G(\boldsymbol{h}, N, t) - \beta(\boldsymbol{h}, N)F(\boldsymbol{h}, N, t)\,, \quad (9)$$

where $\beta(\boldsymbol{h}, N)$, the "chain-breakage coefficient", is the probability of breakage of the chain (junction), and $G(\boldsymbol{h}, N, t)$, the "chain-reformation function", is the instantaneous distribution function of chains reformed at time t.

For actual calculations, however, the following integral form of the chain-distribution function is more convenient than the above differential form:

$$|\boldsymbol{e}(t)|F(\boldsymbol{h}, N, t)=F_0(\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\exp\left[-\int_0^t \beta(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\,dt'\right] + \int_0^t |\boldsymbol{e}(t')|G(\boldsymbol{e}(t')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N, t')\exp\left[-\int_{t'}^t \beta(\boldsymbol{e}(t'')\boldsymbol{e}^{-1}(t)\boldsymbol{h}, N)\,dt''\right]dt'\,. \quad (10)$$

§ 3. Shearing Stress and Viscosity Coefficient

Let the bulk of a given system flow in the x-direction with a constant velocity gradient λ in the y-direction. The strain tensor for this deformation is

$$\boldsymbol{e}(t)=\begin{pmatrix} 1 & \lambda t & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \qquad (11)$$

It follows from Eq. (9) that in order to maintain the flow steady, the quantity $(d\boldsymbol{e}/dt)\boldsymbol{e}^{-1}$ must be independent of time. Eq. (11) fulfills this condition. Introduction of this strain tensor into Eq. (10) gives

$$F(\xi, \eta, \zeta;\, N)=F(\xi-\lambda\eta t, \eta, \zeta;\, N)\exp\left[-\int_0^t \beta(\xi-\lambda\eta(t-t'), \eta, \zeta;\, N)\,dt'\right] + \int_0^t G(\xi-\lambda\eta(t-t'), \eta, \zeta;\, N)\exp\left[-\int_{t'}^t \beta(\xi-\lambda\eta(t-t''), \eta, \zeta;\, N)\,dt''\right]dt\,.$$

The time variable t can be eliminated from Eq. (12) by making a transformation

$$\begin{aligned} t' &\longrightarrow \xi' =\xi-\lambda\eta(t-t')\,, \\ t'' &\longrightarrow \xi''=\xi-\lambda\eta(t-t'')\,, \end{aligned} \qquad (13)$$

and letting t to infinity. In this limit,

$$|\xi-\lambda\eta t|\to\infty\,, \qquad F(\xi-\lambda\eta t, \eta, \zeta;\, N)\to 0\,, \qquad (14)$$

so that we have

$$F(\xi, \eta>0, \zeta;\, N)=\frac{1}{\lambda\eta}\int_{-\infty}^{\xi} G(\xi', \eta, \zeta;\, N)\exp\left[-\frac{1}{\lambda\eta}\int_{\xi'}^{\xi} \beta(\xi'', \eta, \zeta;\, N)\,d\xi''\right]d\xi'\,, \qquad (15)_1$$

$$F(\xi, \eta<0, \zeta;\, N)=\frac{1}{\lambda|\eta|}\int_{-\infty}^{-\xi} G(\xi', |\eta|, \zeta;\, N)\exp\left[-\frac{1}{\lambda|\eta|}\int_{\xi'}^{-\xi} \beta(\xi'', \eta, \zeta;\, N)\,d\xi''\right]d\xi'\,, \qquad (15)_2$$

where we have used the relation

$$G(\xi, \eta, \zeta;\, N)=G(-\xi, -\eta, \zeta;\, N)\,. \qquad (16)$$

This holds here because the flow occurs in the plane normal to the z-direction, so that in the symmetry condition $G(\boldsymbol{h}, N)=G(-\boldsymbol{h}, N)$ ζ may be replaced by $-\zeta$. It is readily shown that this condition results in

$$F(\xi, \eta, \zeta; N)=F(-\xi, -\eta, \zeta; N) \tag{17}$$

which, in turn, reduces the integration of Eq. (7) with respect to $\boldsymbol{h}$ to that only in the half-space $\Omega'(\eta>0)$.

Substitution of Eq. (16) into Eq. $(15)_1$, use of Eq. (7) and the definition

$$\mu=\sigma_{12}/\lambda \tag{18}$$

give the viscosity coefficient μ. Exchange of the order of integration, exchange of symbols ξ and ξ', and transformation of the variables such that

$$\begin{aligned} \xi' &\longrightarrow \theta=\xi'/|\xi| , \\ \xi'' &\longrightarrow \theta'=\xi''/|\xi| , \end{aligned} \tag{19}$$

thus provide

$$\begin{aligned} \mu(\lambda)=2\cdot\frac{3kT}{a^2}\sum_N\frac{1}{N}\iiint_{\Omega''}\frac{\xi^2}{\lambda^2}\Big[&G(\xi, \eta, \zeta; N)\int_1^\infty\theta\exp\left\{-\frac{\xi}{\lambda\eta}\int_1^\theta\beta(\xi\theta', \eta, \zeta; N)d\theta'\right\}d\theta \\ &+G(-\xi, \eta, \zeta; N)\int_{-1}^\infty\theta\exp\left\{-\frac{\xi}{\lambda\eta}\int_{-1}^\theta\beta(\xi\theta', \eta, \zeta; N)d\theta'\right\}d\theta\Big]d\boldsymbol{h} , \end{aligned} \tag{20}$$

where Ω'' denotes the quartary space, $\xi>0$ and $\eta>0$. Furthermore, if $G(\boldsymbol{h}, N)$ and $\beta(\boldsymbol{h}, N)$ are spherically symmetric, Eq. (20) may be simplified to

$$\mu(\lambda)=\frac{3kT}{2a^2}\sum_N\frac{1}{N}\iiint_\Omega\xi^2G(\boldsymbol{h}, N)J(\boldsymbol{h}, N, \lambda)d\boldsymbol{h} , \tag{21}$$

where

$$J(\boldsymbol{h}, N, \lambda)=J_+(\boldsymbol{h}, N, \lambda)+J_-(\boldsymbol{h}, N, \lambda) , \tag{22}$$

$$J_\pm(\boldsymbol{h}, N, \lambda)=\frac{1}{\lambda^2}\int_{\pm1}^\infty\theta\exp\left[-\frac{1}{\lambda}\left|\frac{\xi}{\eta}\right|\int_{\pm1}^\theta\beta(\xi\theta', \eta, \zeta; N)d\theta'\right]d\theta . \tag{23}$$

No more reduction of these equations may be made without actual information about $G(\boldsymbol{h}, N)$ and $\beta(\boldsymbol{h}, N)$ for given values of λ. In the vicinity of such limiting λ-values as $\lambda\to0$ and $\lambda\to\infty$, asymptotic forms of the viscosity coefficient are obtained:

i) For sufficiently small value of λ, μ may be expanded in powers of λ to give

$$\mu(\lambda)=\mu_0+\mu_1\lambda+\mu_2\lambda^2+\cdots . \tag{24}$$

Simple but lengthy calculation determines the expansion coefficients $\mu_0, \mu_1, \mu_2, \cdots$ in the form (Appendix A):

$$\begin{aligned} \mu_0&=\frac{3kT}{a^2}\sum_N\frac{1}{N}\iiint_\Omega\eta^2\frac{G(\boldsymbol{h}, N)}{\beta^2(\boldsymbol{h}, N)}\left[1-\frac{\xi}{\beta}\frac{\partial\beta}{\partial\xi}\right]d\boldsymbol{h} \\ &=\frac{3kT}{a^2}\frac{4}{3}\pi\sum_N\frac{1}{N}\int_0^\infty r^4\frac{G(r, N)}{\beta^2(r, N)}\left[1-\frac{1}{5}\frac{r}{\beta(r, N)}\frac{d\beta(r, N)}{dr}\right]dr , \end{aligned} \tag*{$(25)_1$}$$

$$\mu_1=0 , \tag*{$(25)_2$}$$

$$\begin{aligned} \mu_2=-\frac{3kT}{a^2}\sum_N\frac{1}{N}\iiint_\Omega\frac{\eta^4}{\xi^2}\frac{G(\boldsymbol{h}, N)}{\beta^4(\boldsymbol{h}, N)}\Big[&\frac{\xi^3}{\beta}\frac{\partial^3\beta}{\partial\xi^3}+4\frac{\xi^2}{\beta}\frac{\partial^2\beta}{\partial\xi^2} \\ &-10\left(\frac{\xi^2}{\beta}\frac{\partial^2\beta}{\partial\xi^2}\right)\left(\frac{\xi}{\beta}\frac{\partial\beta}{\partial\xi}\right)-15\left(\frac{\xi}{\beta}\frac{\partial\beta}{\partial\xi}\right)^2+15\left(\frac{\xi}{\beta}\frac{\partial\beta}{\partial\xi}\right)^3\Big]d\boldsymbol{h} \end{aligned} \tag*{$(25)_3$}$$

$$=-\frac{3kT}{a^2}\frac{4}{3}\pi\frac{1}{35}\sum_N\frac{1}{N}\int_0^\infty r^4\frac{G(r,N)}{\beta^4(r,N)}\left[\frac{r^3}{\beta}\frac{d^3\beta}{dr^3}+18\frac{r^2}{\beta}\frac{d^2\beta}{dr^2}+66\frac{r}{\beta}\frac{d\beta}{dr}\right.$$
$$\left.-10\frac{r^3}{\beta^2}\frac{d\beta}{dr}\frac{d^2\beta}{dr^2}-65\left(\frac{r}{\beta}\frac{d\beta}{dr}\right)^2+15\left(\frac{r}{\beta}\frac{d\beta}{dr}\right)^3\right]dr\,.$$

ii) To obtain an asymptotic expression of μ for sufficiently large λ it is assumed that for sufficient large r-value $\beta(r, N)$ varies approximately proportional to the nth power of r, that is,

$$\lim_{r\to\infty}\beta(r,N)\longrightarrow Ar^n\,. \tag{26}$$

It follows then that

$$\lim_{\lambda\to\infty}\mu(\lambda)\longrightarrow\begin{cases}\infty\\ \text{finite}\\ 0\end{cases} \tag{27}$$

in accordance with the condition

$$(-1<)n\gtreqless 0\,, \tag{28}$$

respectively. (Appendix. B)

§ 4. Tensile Stress and Tensile Viscosity

Making use of a similar procedure as described above permits calculation of the tensile stress and the tensile viscosity. Let us consider an incompressible sample being stretched in the x-direction. The strain tensor for this deformation is

$$\boldsymbol{e}=\begin{pmatrix}\alpha & 0 & 0\\ 0 & 1/\sqrt{\alpha} & 0\\ 0 & 0 & 1/\sqrt{\alpha}\end{pmatrix} \tag{29}$$

The condition of steady state, $(d\boldsymbol{e}/dt)\boldsymbol{e}^{-1}=\text{const.}$, leads $\alpha(t)$ to the form

$$\alpha(t)=\alpha_0 e^{\lambda^* t}=e^{\lambda^* t}\,, \tag{30}$$

where it has been chosen that $\alpha(0)=1$ at $t=0$.

In that follows, we are interested only in the normal components of the stress, which contain the isotropic hydrodynamic inner pressure P. In the present theory of network structure, P is rather an integration constant to be determined from the boundary condition. The boundary condition is that the side of the sample is free from external force; this gives $\sigma_{22}=\sigma_{33}=0$. Combination of Eqs. (6) and (7) then results in

$$P=-\frac{3kT}{a^2}\sum_N\frac{1}{N}\iiint\begin{pmatrix}\eta^2\\ \text{or}\\ \zeta^2\end{pmatrix}F(\boldsymbol{h},N)d\boldsymbol{h}\,, \tag{31}$$

which readily leads to the tensile stress $\sigma^*=\sigma_{11}$ in the form

$$\sigma^*=\frac{3kT}{2a^2}\sum_N\frac{1}{N}\iiint(2\xi^2-\eta^2-\zeta^2)F(\boldsymbol{h},N)d\boldsymbol{h}\,. \tag{32}$$

We introduce into Eq. (10) the new integral variables $\xi'=e^{\lambda^* t'}\xi_0$ and $\xi''=e^{\lambda^* t''}\xi_0$ in place of t' and t'', respectively, and let t go to infinity, taking into account that

$$\lim_{t\to\infty}\boldsymbol{h}_0=\lim_{t\to\infty}(\xi_0,\eta_0,\zeta_0)=(0,\infty,\infty)\,,$$
$$\lim_{t\to\infty}F(\boldsymbol{h}_0,N)=0\,. \tag{33}$$

Remembering further that $\sqrt{\xi_0}\eta_0=\sqrt{\xi}\,\eta$ and $\sqrt{\xi_0}\zeta_0=\sqrt{\xi}\,\zeta$, the final expression of the steady chain-distribution function reads

$$F(\boldsymbol{h}, N)=\frac{1}{\lambda^*}\int_0^{\xi}\frac{1}{\xi'}G\left(\xi', \sqrt{\frac{\xi}{\xi'}}\eta; \sqrt{\frac{\xi}{\xi'}}\zeta; N\right)\exp\left[-\frac{1}{\lambda^*}\int_{\xi'}^{\xi}\beta\left(\xi'', \sqrt{\frac{\xi}{\xi''}}\eta, \sqrt{\frac{\xi}{\xi''}}\zeta; N\right)d\xi''\right]d\xi' . \tag{34}$$

As in the treatment of shearing flow, Eq. (34) is substituted into Eq. (32), and suitable transformation of the intergral variables and exchange of the order of integration are made. We then obtain

$$\sigma^*=\frac{3kT}{a^2}\frac{1}{\lambda^*}\Sigma_N\frac{1}{N}\iiint_{\Omega'}G(\boldsymbol{h}, N)d\boldsymbol{h}\int_{\xi}^{\infty}\frac{1}{\xi'}\left(2\xi'^2-\frac{\xi}{\xi'}\eta^2-\frac{\xi}{\xi'}\zeta^2\right)$$
$$\times\exp\left[-\frac{1}{\lambda^*}\int_{\xi}^{\xi'}\frac{1}{\xi''}\beta\left(\xi'', \sqrt{\frac{\xi}{\xi''}}\eta, \sqrt{\frac{\xi}{\xi''}}\zeta; N\right)d\xi''\right]d\xi' ,$$

where Ω' is the half-space $\xi>0$.

Because of cylindrical symmetry, it is convenient to use the cylindrical coordinate

$$(\xi, \eta, \zeta)\longrightarrow(\xi, \rho, \varphi) . \tag{36}$$

In terms of the dimensionless variables

$$\theta=\xi'/\xi \qquad \text{and} \qquad \theta'=\xi''/\xi \tag{37}$$

the tensile viscosity coefficient defined by Eq. (4) is then written

$$\mu^*(\lambda^*)=\frac{3kT}{a^2}\Sigma_N\frac{1}{N}L(N, \lambda^*) , \tag{38}$$

where

$$L(N, \lambda^*)=2L_1(N, \lambda^*)-L_2(N, \lambda^*) , \tag{39}$$

$$L_{1,2}(N, \lambda^*)=\frac{2\pi}{\lambda^{*2}}\int_0^{\infty}d\xi\int_0^{\infty}d\rho\begin{pmatrix}\xi^2\\ \rho^2\end{pmatrix}\rho G(\xi, \rho; N)M_{1,2}(\xi, \rho; N; \lambda^*) , \tag{40}$$

and

$$M_{1,2}(\xi, \rho; N; \lambda^*)=\int_1^{\infty}\begin{pmatrix}\theta\\ 1/\theta^2\end{pmatrix}\exp\left[-\frac{1}{\lambda^*}\int_1^{\theta}\frac{1}{\theta'}\beta(\xi\theta', \rho/\sqrt{\theta'}; N)d\theta'\right]d\theta . \tag{41}$$

The double subscripts 1 and 2 refer to the above and below factors in the parenthesis of the integrand, respectively.

For the two limiting cases, $\lambda^*\to0$ and $\lambda^*\to\infty$, the asymptotic forms are derived as follows:

i) For $\lambda^*\to0$,

$$\mu^*(\lambda^*)=\mu_0^*+\mu_1^*\lambda^*+\mu_2^*\lambda^{*2}+\cdots , \tag{42}$$

$$\mu_0^*=\frac{3kT}{a^2}\cdot4\pi\,\Sigma_N\frac{1}{N}\int_0^{\infty}r^4\frac{G(r, N)}{\beta^2(r, N)}\left[1-\frac{1}{5}\frac{r}{\beta}\frac{d\beta}{dr}\right]dr , \tag*{$(43)_1$}$$

$$\mu_1^*=\frac{3kT}{a^2}\cdot4\pi\,\Sigma_N\frac{1}{N}\int_0^{\infty}r^4\frac{G(r, N)}{\beta^3(r, N)}\left[1-\frac{33}{35}\frac{r}{\beta}\frac{d\beta}{dr}-\frac{2}{35}\left\{\frac{r^2}{\beta}\frac{d^2\beta}{dr^2}-3\left(\frac{r}{\beta}\frac{d\beta}{dr}\right)^2\right\}\right]dr , \tag*{$(43)_2$}$$

$$\mu_2^*=\frac{3kT}{a^2}\cdot12\pi\,\Sigma_N\frac{1}{N}\int_0^{\infty}r^4\frac{G(r, N)}{\beta^4(r, N)}\left[1-\frac{311}{105}\frac{r}{\beta}\frac{d\beta}{dr}-\frac{4}{7}\frac{r^2}{\beta}\frac{d^2\beta}{dr^2}+\frac{43}{21}\left(\frac{r}{\beta}\frac{d\beta}{dr}\right)^2\right.$$
$$\left.-\frac{1}{35}\left\{\frac{r^3}{\beta}\frac{d^3\beta}{dr^2}-10\left(\frac{r^2}{\beta}\frac{d^2\beta}{dr^2}\right)\left(\frac{r}{\beta}\frac{d\beta}{dr}\right)+15\left(\frac{r}{\beta}\frac{d\beta}{dr}\right)^3\right\}\right]dr . \tag*{$(43)_3$}$$

ii) For $\lambda^*\to\infty$,
if it is assumed that asymptotically

$$\lim_{r\to\infty}\beta(r, N)\longrightarrow Ar^n\,, \tag{44}$$

there is obtained

$$\lim_{\lambda^*\to\infty}\mu^*(\lambda^*)\longrightarrow\begin{cases}\infty\\ \text{finite}\\ 0\end{cases} \tag{45}$$

in accordance with

$$(0<)n\gtreqless 1\,. \tag{46}$$

§ 5. Chain Breakage Coefficient of the Square-Well Type

Let us consider a chain-breakage coefficient $\beta(r, N)$ of the square-well type

$$\beta(r, N)=\begin{cases}\beta_0 & r<R\\ \infty & r\geq R\,,\end{cases} \tag{47}$$

This type indicates that chains reformed at r larger than R immediately break off. Hence it can be assumed that the chain-reformation function $G(r, N)$ vanishes for $r\geq R$. Application of Eq. (47) brings the shearing viscosity Eq. (21) to the form

$$\mu(\lambda)=\frac{3kT}{a^2}\frac{1}{\beta_0{}^2}\Sigma_N\frac{1}{N}\iiint_\Omega G(\boldsymbol{h}, N)\Big[\eta^2\Big\{1-\exp\Big[-\frac{\beta_0}{\lambda|\eta|}(\xi_0-\xi)\Big]\Big\}$$
$$+\frac{\beta_0}{\lambda}|\eta|\Big\{\xi-\xi_0\exp\Big[-\frac{\beta_0}{\lambda|\eta|}(\xi_0-\xi)\Big]\Big\}\Big]d\boldsymbol{h}\,, \tag{48}$$

where ξ_0 is connected with R, η and ζ by

$$\xi_0{}^2+\eta^2+\zeta^2=R^2\,. \tag{49}$$

Fig. 1 shows schematically the rate-dependence of viscosity as estimated from the integrand of Eq. (48) as a function of λ. The curve horizontally enters the μ-axis, which means the Newtonian flow to appear at the limit of sufficiently small velocity-gradients, in agreement with the finding from Eqs. (24) and (25). Viscosity decreases with increasing rate of flow and appears to approach zero in inverse proportion of the square of λ for sufficiently large values of it.

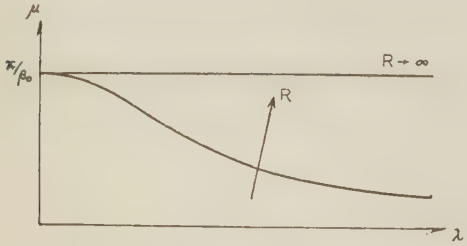

Fig. 1. Structural Viscosity.

If the chain-breakage coefficient is constant, i.e., if $R\to\infty$ in Eq. (47), viscosity is independent of rate of flow, as has been shown by Green-Tobolsky,[3] that is

$$\mu(\lambda)=\frac{3kT}{a^2}\frac{1}{\beta_0{}^2}\Sigma_N\frac{1}{N}\iiint_\Omega\eta^2G(\boldsymbol{h}, N)d\boldsymbol{h}$$
$$=\kappa/\beta_0 \tag{50}$$

where κ denotes the instantaneous elastic modulus for simple shear deformation.

For the simple stretching, the expression of tensile viscosity with the chain-breakage coefficient of the square-well type is so complex that complete rate-dependence of such viscosity is not ready to follow. However, it is shown, taking Eqs. (42)∼(46) into consideration that

i) the tensile viscosity vs. rate of stretching curve enters the μ^*-axis with a finite (positive) slope;

ii) for $\lambda^*\to\infty$, $\mu^*(\lambda^*)\to 0$. (51)

It is also shown that for constant chain-breakage coefficient $\mu^*(\lambda^*)$ goes to infinity if stretching rate λ^* exceeds the value $\beta_0/2$ (the divergent term is M_2 in Eq. (41)). Then the tensile viscosity would vary with rate of stretching as shown in Fig. 2. This curve has a maximum and shows the "inverse structural viscosity" in the range of small λ^*; this behavior may be found in the experimental data of Nitchmann and Schrade.[4]

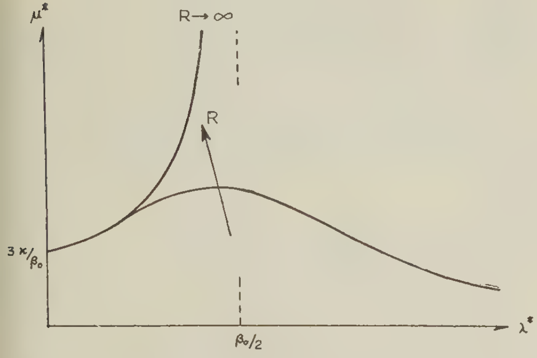

Fig. 2. Tensile Viscosity.

Although the theoretical interpretation of the abnormal viscosity given above appears satisfactory at least qualitatively, it is rather an accident. Use of a different form for the chain-breakage coefficient results in a $\mu-\lambda$ relation of different behavior. There is a type of β in which viscosity increases with velocity gradient even in the shearing flow. This behavior may be compared to that often called "dilatancy". The actual mechanisms of dilatancy may be much more complicated than what we are considering here. For such system the quantities appeared in our theory may have no direct physical meanings even if the theoretical results are consistent with experimental ones.

§ 6. Comparison between Two Viscosities $\mu(\lambda)$ and $\mu^*(\lambda^*)$

As has been shown in the above section, the rate-dependence of the shearing viscosity is entirely different from that of the tensile viscosity. However, there may be a close connection between them because the dissipative mechanism is the same in both deformations. In the introductory section we pointed out that classical phenomenological theory leads to a simple interrelation between the shearing and tensile viscosity coefficients of the ideal, Newtonian fluid, that is, "Trouton's formula" $\mu^*=3\mu$. This relation is in general not valid in our network theory. At the limit of small rate of deformation, however, there obtains

$$\lim_{\lambda^*\to 0}\mu^*(\lambda^*)=3\lim_{\lambda\to 0}\mu(\lambda) \qquad (52)$$

from Eqs. (24), (25), (42) and (43).

The fact that the shearing viscosity curve horizontally intersects the axis comes out of symmetric property in the inversion of the direction of flow. Change of the sign of flow-rate gives the identical flow in the opposite direction, and the viscosity coefficient must therefore be symmetric about the μ-axis. This means that the shearing viscosity intersects the ordinate horizontally when plotted against the rate of shear. This is not the case with simple strectching deformation. A positive value of λ^* corresponds to a simple stretching, and a negative to a simple compressing deformation. Any simple symmetric property does not obtain in this type of deformation.

The rate-dependence may be more pronounced for tensile viscosity than for shearing viscosity. This fact is understood if we consider the relative degree of orientation of network chains in both stationary flows. In shearing flow, the network chains may be oriented in the flow direction in proportion to the time, so far as the chain-breakage does not take place. If the value of β is independent of chain-stretching, the average orientation of chains would be proportional to the rate of flow λ, and thus the system shows the Newtonian flow. On the other hand, the orientation of chains in simple stationary stretching may increase exponentially with time (see Eq. (30)). If λ^* approaches the value $\beta/2$ with constant β, certain numbers of chains may be elongated infinity without breakage. This results in getting the tensile viscosity diversed at $\lambda^*=\beta/2$. In actual systems, however, β may increase with the end-to-end distance of a chain, and chains will break down at finite elongations.

§ 7. Summary

Viscosity coefficients of concentrated polymer solutions are discussed assuming a Gaussian weak network with the chain-breakage (c-b-) coefficient as an arbitrary function of elongation of a chain. The c-b-coefficient of square-well type yields the typical rate-dependent shearing and tensile viscosities. However, some other choices of the form of the c-b-coefficient lead to physically meaningless results. For example, the form that $\beta(r, N)=$

$Ar^n, n>5$ gives a negative viscosity coefficient for small values of velocity gradient. Then, there should exist some physical restrictions on the allowable functional form of the c-b-coefficient. This problem is beyond the scope of the present paper.

The dependence of viscosity on molecular weight is another problem of extreme interest on concentrated solutions of polymers. Recent experiments demonstrate that the viscosity increases with the 3.4th power of molecular weight and that this dependence is practically independent of polymer species if M.W. and concentration of highpolymer are not so low. Unfortunately, introduction of the concept of molecular weight into our network model seems to be so difficult that at present we must await a further development of the theory for the interpretation of such behavior.

Acknowledgments

The author would express his sincere thanks to Professor T. Yamamoto, Dr. E. Teramoto and the members of Research Group of High Polymer in Kyoto for their encouragement and valuable discussions. He is further obliged to Professor H. Fujita for his kindly amendment of the munuscript, Miss F. Iizuka for a trial of lengthy calculation and Misses M. Matsuda and M. Eto for the preparation of the munuscript. The present investigations has been supported partly by the Scientific Research Grant of the Ministry of Education.

Appendix A

Let us consider the viscosity coefficient $\mu(\lambda)$ for sufficiently small value of velocity gradient λ. The exponential factors in the integrands of $J\pm(\boldsymbol{h}, N, \lambda)$ (Eq. (22)) become negligible for θ not extremely close to ±1 except for particular values of ξ, η and β. For sufficiently small λ, there is a small positive number Δ which satisfies the condition

$$\Delta/\lambda \gg 1 \quad \text{and} \quad \Delta^2/\lambda \ll 1 \tag{A.1}$$

(The first condition is more important; so far as $\beta(\boldsymbol{h}, N)$ is not so singular, the second condition may be ignored.) Use of the new integral variables $t=\theta\mp1$ etc. reduces Eq. (23) to

$$J_\pm(\boldsymbol{h}, N, \lambda)=\frac{1}{\lambda^2}\int_0^\Delta (t\pm1)\exp\Bigg[-\frac{1}{\lambda}\left|\frac{\xi}{\eta}\right|$$

$$\times\int_0^t \beta(\xi(t'\pm1), \eta, \zeta; N)dt'\Bigg]dt+\varepsilon_\pm, \tag{A.2}$$

$$\varepsilon_\pm \sim P(\Delta/\lambda)e^{-(\Delta/\lambda)\bar{\beta}}, \tag{A.3}$$

where $P(x)$ is a polynomial of finite order of x and $\bar{\beta}$ is a "representative value" of $\beta(\boldsymbol{h}, N)$. As λ becomes sufficiently small and Δ/λ very large, $\varepsilon_\pm$ may approach zero. It is assumed that $\beta(\xi(t'\pm1), \eta, \zeta; N)$ can be expanded about the point $\boldsymbol{h}=(\xi, \eta, \zeta)$ in powers of t' which is confined to the range $0\sim\Delta$ Thus

$$\beta(\xi(t'\pm1); \eta, \zeta; N)$$
$$=\beta_\pm+\frac{1}{1!}\left[\frac{\partial\beta}{\partial\xi}\right]_\pm \xi t'+\frac{1}{2!}\left[\frac{\partial^2\beta}{\partial\xi^2}\right]_\pm \xi^2 t'^2+\cdots \tag{A.4}$$

where the following abbreviations are used:

$$\left.\begin{aligned}\beta_\pm&=\beta(\pm\xi, \eta, \zeta; N),\\ \left[\frac{\partial^n\beta}{\partial\xi^n}\right]_\pm&=\left[\frac{\partial^n\beta(\boldsymbol{h}, N)}{\partial\xi^n}\right]_{\xi=\pm\xi}.\end{aligned}\right\} \tag{A.5}$$

Substitution of Eq. (A.4) into Eq. (A.2), and carrying out of the integration with respect to t' give the series expansion of the exponential in powers of t $(0<t<\Delta)$ except for the factor of which exponent has the factor $\beta_\pm t$. That is

$$J_\pm(\boldsymbol{h}, N, \lambda)$$
$$=\frac{1}{\lambda^2}\int_0^\Delta (t\pm1)\exp\left(-\frac{1}{\lambda}\left|\frac{\xi}{\eta}\right|\beta_\pm t\right)[\cdots]dt+\varepsilon_\pm, \tag{A.6}$$

where $[\cdots]$ is the abbreviation of the power series of t. Replacement of Δ by ∞, which may give rise to a negligible contribution to the integral, reduces Eq. (A.6) to

$$J_\pm(\boldsymbol{h}, N, \lambda)$$
$$=\frac{1}{\lambda^2}\Bigg[\pm\left|\frac{n}{\xi}\right|\frac{\lambda}{\beta_\pm}+\left(\frac{\eta}{\xi}\right)^2\{1\mp D_\pm\beta\}\frac{\lambda^2}{\beta_\pm{}^2}$$
$$-\left|\frac{\eta}{\xi}\right|^3\{3D_\pm\beta\pm D_\pm{}^2\beta\mp3(D_\pm\beta)^2\}\frac{\lambda^3}{\beta_\pm{}^3}$$
$$-\left(\frac{\eta}{\xi}\right)^4\{4D_\pm{}^2\beta\pm D_\pm{}^3\beta\mp10(D_\pm\beta)(D_\pm{}^2\beta)$$
$$-15(D_\pm\beta)^2\pm15(D_\pm\beta)^3\}\frac{\lambda^4}{\beta_\pm{}^4}+O(\lambda^5)\Bigg], \tag{A.7}$$

where

$$D_\pm{}^n\beta=\frac{\xi^n}{\beta_\pm}\left[\frac{\partial^n\beta}{\partial\xi^n}\right]_{\xi=\pm\xi}. \tag{A.8}$$

If $\beta(\boldsymbol{h}, N)$ is spherically symmetric,

$$D_\pm{}^n\beta\fallingdotseq(-)^n\frac{\xi^n}{\beta}\left[\frac{\partial^n\beta}{\partial\xi^n}\right]\equiv(-)^n D^n\beta. \tag{A.9}$$

The final expression of $J(\boldsymbol{h}, N, \lambda)$ is thus

$$J(\boldsymbol{h}, N, \lambda)=2\left(\frac{\eta}{\xi}\right)^2\frac{1}{\beta^2}[1-D\beta]$$
$$-2\left(\frac{\eta}{\xi}\right)^4\frac{1}{\beta^4}[D^3\beta+4D^2\beta-10(D^2\beta)(D\beta)$$
$$-15(D\beta)^2+15(D\beta)^3]\lambda^2+O(\lambda^4)\ . \quad (A.10)$$

Substitution of Eq. (A.10) into Eq. (21) permits integration of $\mu(\lambda)$ with respect to the angular components of $\boldsymbol{h}$ under the assumption of the spherically symmetric chain-reformation function $G(\boldsymbol{h}, N)$. The final expressions are Eqs. (24) and (25).

The similar calculation can be made for the tensile viscosity to yield Eqs. (42) and (43).

Appendix B

If the spherically symmetric chain-breakage coefficient $\beta(\boldsymbol{h}, N)$ is a smooth function of $\boldsymbol{h}$, it may be assumed that $\beta(\boldsymbol{h}, N)$ varies approximately proportional to the nth power of $|\boldsymbol{h}|=r$ for sufficiently large r. Namely, there is a quantity R for any positive ε such that for $r>R$

$$\left|\frac{\beta(r, N)}{A(N)r^n}-1\right|<\varepsilon \quad (B.1)$$

or

$$A(N)r^n(1-\varepsilon)<\beta(r, N)$$
$$<A(N)r^n(1+\varepsilon)\ . \quad (B.2)$$

When $r\leq R$, on the other hand, we define the quantity $B(R)$ by

$$B(R)=\mathrm{Max}_{(r\leq R)}\{\beta(r, N),\ A(N)(1+\varepsilon)r^n\}\ . \quad (B.3)$$

Let us consider the integral

$$K_\pm(\theta)=\int_{\pm1}^{\theta}\beta(\xi\theta', \eta, \zeta\,;N)d\theta'\ . \quad (B.4)$$

For sufficiently large R, Θ may be chosen such that

$$R^2=\xi^2\Theta^2+\eta^2+\zeta^2\simeq\xi^2\Theta^2\ . \quad (B.5)$$

The correction for the approximation involved may, if necessary, be included in ε. It then follows that

i) For $\theta<\Theta$,

$$0<K_\pm(\theta)<B(\Theta+1)\ , \quad (B.6)$$

ii) For $\theta>\Theta$,

$$\frac{A}{1+n}(1-\varepsilon)\xi^n\Theta^{n+1}-B(\Theta+1)$$
$$<K_\pm(\theta)<\frac{A}{1+n}(1+\varepsilon)\xi^n\theta^{n+1}+B(\Theta+1)\ . \quad (B.7)$$

Use of abbreviations

$$\frac{A}{1+n}\xi^n=a' \quad \text{and} \quad B(\Theta+1)=b' \quad (B.8)$$

and substitution of Eqs. (B.6) and (B.7) into Eq. (23) results in

$$J_\pm(\boldsymbol{h}, N, \lambda)=\frac{1}{\lambda^2}\left[\int_{\pm1}^{\Theta}+\int_{\Theta}^{\infty}\right]>\frac{1}{\lambda^2}\int_{\Theta}^{\infty}$$
$$>\frac{1}{\lambda^2}\left[\int_0^{\infty}\theta\exp\left[-\frac{1}{\lambda}\left|\frac{\xi}{\eta}\right|(a'(1+\varepsilon)\theta^{n+1}+b')\right]d\theta-\int_0^{\Theta}\theta d\theta\right], \quad (B.9)$$
$$J_\pm(\boldsymbol{h}, N, \lambda)<\frac{1}{\lambda^2}\left[\int_0^{\infty}\theta\exp\left[-\frac{1}{\lambda}\left|\frac{\xi}{\eta}\right|(a'(1-\varepsilon)\theta^{n+1}-b')\right]d\theta+\int_0^{\Theta}\theta d\theta\right]. \quad (B.10)$$

These integrations are evaluated under the condition $n>-1$ to give

$$\frac{1}{\lambda^2}\left[e^{-b/\lambda}\frac{1}{n+1}\Gamma\left(\frac{2}{n+1}\right)\left(\frac{\lambda}{a(1+\varepsilon)}\right)^{\frac{2}{1+n}}-\frac{\Theta^2}{2}\right]<J_\pm(\boldsymbol{h}, N, \lambda)$$
$$<\frac{1}{\lambda^2}\left[e^{+\frac{b}{\lambda}}\frac{1}{n+1}\Gamma\left(\frac{2}{n+1}\right)\left(\frac{1}{a(1-\varepsilon)}\right)^{\frac{2}{1+n}}+\frac{\Theta^2}{2}\right]. \quad (B.11)$$

where

$$\left|\frac{\xi}{\eta}\right|a'\equiv a \quad \text{and} \quad \left|\frac{\xi}{\eta}\right|b'\equiv b\ . \quad (B.12)$$

Limiting processes λ and $\Theta\to\infty$ with $\Theta/\lambda\to0$ and $b/\lambda\to0$ give the final expression

$$\lim_{\lambda\to\infty}J_\pm(\boldsymbol{h}, N, \lambda)$$
$$=\frac{1}{n+1}\Gamma\left(\frac{2}{n+1}\right)a^{-2/(n+1)}\lambda^{-2n/(n+1)}\ . \quad (B.13)$$

Use of Eq. (B.13) in Eq. (21) finally leads to the limiting value of the viscosity as appeared in Eq. (27) with Eq. (28).

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 10, OCTOBER, 1957

On the Piezoelectric Effect of Bone

By Eiichi FUKADA

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

and Iwao YASUDA

Department of Orthopaedic Surgery, Kyoto Prefectural Medical University, Kamikyo-ku, Kyoto

(Received August 15, 1956, Revised July 9, 1957)

The piezoelectric effect of bone has been observed similarly to the case of wood or ramie. The specimens were cut out from the femur of man and ox, and dried completely by heating. The piezoelectric constants were measured by three different experiments, that is, measurements of the static direct effect, the dynamic direct effect and the dynamic converse effect. The piezoelectric effect appears only when the shearing force is applied to the collagen fibres to make them slip past erch other. The magnitude of piezoelectric constant depends on the angle between the applied pressure and the axis of the bone. The maximum value of piezoelectric constant amounts to 6×10^{-9} c.g.s. e.s.u., which is about one-tenth of a piezoelectric constant d_{11} of quarts crystal. The specimens which were boiled in hot water and afterwards dried completely showed little change in the piezoelectric effect, the fact ascertaining that the effect is not of biological origin. The origin to piezoelectricity in bone may be ascribed to the piezoelectric effect of the crystalline micelle of collagen molecules. The consideration of the symmetry of the configulation of collagen fibres in the bone texture shows the existence of effects which are represented by only two piezoelectric constants d_{14} and d_{25}, which are the same in magnitude but opposite in sign.

§ 1. Introduction

In previous papers it has been shown that the piezoelectric effect is observed in wood[1)2)], wool and hair[3)]. Recently Fukada has succeeded in confirming the direct and converse piezoelectric effects in wood[4)] and ramie[5)]. The piezoelectric effect in these materials is due to the crystalline properties of cellulose micelle which are highly orientated in the direction of the fibre axis.

Yasuda has been studying the dynamic properties of bone for some years[6)] and has found that the piezoelectric effect is observed in bone[7)]. The authors have undertaken the quantitative measnrement of the piezoelectric constants of bone by means of both direct and converse piezoelectric effect.

§ 2. Specimens

The bone of femur is comprised of outer hard layers of collagen and inner soft tissues. If one takes out these tissues, the most parts of bone look like a hollow cylinder except both ends which have peculiar shapes. It is mainly composed of highly orientated collagen fibres and inorganic crystals, called apatite, imbedded among collagen fibres. The axis of bone is designated as the direction of length of the cylinder. The large arrow shown in Fig. 1 is the axis of bone thus defined. The collagen fibres make the spiral structure along the axis and the direction of winding of spiral is reversed to right and left by each successive layers which compose the outer cylinder. Thus the properties of bone is assumed to be symmetrical to this axis.

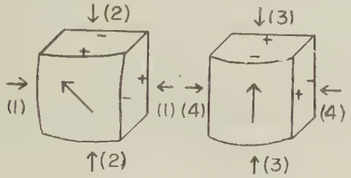

Fig. 1. Specimens of bone. Signs represent those of electric polarization which appear in square planes when pressure is applied on each side plane.

Small square plates of bone as shown in Fig. 1 were cut out from the outer layer of the femur of a man and an ox. The length of the edge of square plates was about 90 to 15 mm. The thickness was about 2 to 3 mm. Specimens obtained from the femus of man had been air-dried for years and were dried for a week or so in a desicater containing calcium chloride before measurements. Specimens obtained from the femur of ox were heated up to about 120°C for about 5 hours for drying. Some specimens were boiled in the hot water for about 2 hours and then dried by the same way.

Very thin silver foils were attached to the square planes by means of alcoholic solution of shellac and those were used as electrodes.

§3. Measuring Apparatus

Measurements of both the direct and converse piezoelectric effect were carried out using the apparatus which was described in the previous paper⁵⁾. The direct effect could be observed easily by the static method. The pressure was applied on the side plane of specimen by a lever mechanism and the electrical charge appeared on the square plane was led to the grid of the UX-54 vacuume tube and the deflection of a galvanometer inserted in the plate circuit was read.

The converse piezoelectric effect could be measured by the dynamical method. The principle of measurement is shown in Fig. 2 schematically. The specimen, an x-cut quartz plate and a completely shielded rochelle salt crystal were clamped together with a metal frame, with polystyrene insulating plates between them. When the electrodes of specimen are earthed and the alternating voltage is applied to the quartz electrodes, the oscillational force is transmitted to the rochelle salt crystal due to the converse piezoelectric effect of quartz. Therefore, the rochelle salt crystal produce the alternating voltage, which can be amplified enough to be read by a voltmeter.

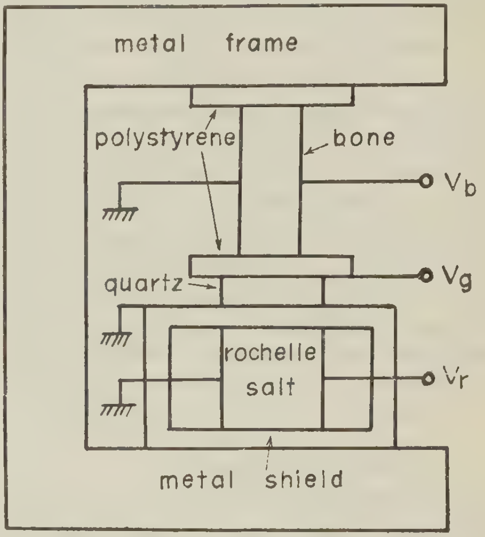

Fig. 2. Schematic diagram of measuring device.

When electrodes of quartz are earthed and a.c. voltage is applied to electrodes of bone specimen, the converse piezoelectric effect of bone can be measured in the same way as in the case of quartz.

If applied voltages V_b and V_q are necessary to cause the same output voltage of rochelle salt crystal in bone and quartz respectively, the piezoelectric constant of bone d_b is given by the following formula:

$$\frac{d_b}{d_q}=\frac{2c}{a}\frac{V_q}{V_b} \qquad (1)$$

where d_q is the piezoelectric constant d_{11} of x-cut quartz crystal and $d_{11}=6.5\times10^{-8}$ c.g.s.

e.s.u., a the height of bone plate, and c the thickness of bone plate.

The frequency of applied voltage is around 2000 c/s. As the size of specimen of bone is very small as described above, the frequency of measurement is sufficiently small compared to the resonance frequency of the specimen. However, a mechanical resonance of the clamped system, presumably due to the outer metal frame, occured by chance around 2000 c/s and the use of this resonance point was very convenient for the measurement. The gain of amplifier was about 100 db. The required voltage applied on the bone specimen was about 100 volts.

The direct piezoelectric effect of bone could be also measured dynamicall by the same apparatus. When electrodes of specimen are earthed and a.c. voltage is applied to the rochelle salt crystal, the oscillating force is transmitted to the quartz and the bone. Then the output voltage of quarts due to the direct piezoelectric effect of quartz plates can be amplified and measured by the voltmeter. On the contrary, when quartz plates are earthed, the bone specimen produces the a.c. output voltage due to the direct piezoelectric effect of bone. The piezoelectric constant of bone can be calculated by the same formula as eq. (1), if we take V_q and V_b to be the necessary applied voltage to rochelle salt crystal in order to obtain the same output voltage of quartz and bone respectively.

§ 4. Experimental Results

Fig. 1 shows the signs of electrical polarization which appear on the square planes when the pressure is applied on each side plane as represented by the small arrows with numbers. The sign and the amount of polarization vary considerably with the direction of pressure. The relation between polarization and applied pressure in the case of direction (1) is represented in Fig. 3. The circles and triangles denote the charge appeared on the bone plate when the pressure is applied and removed respectively. Their signs are, therefore, reverse.

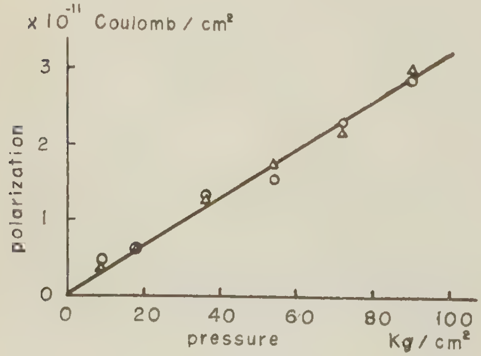

Fig. 3. The direct piezoelectric effect of bone.

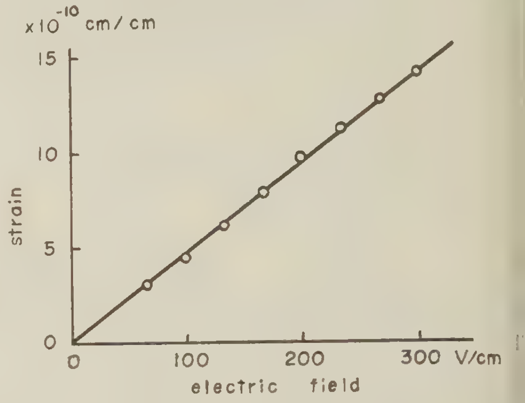

Fig. 4. The converse piezoelectric effect of bone.

The strain vs. applied electric field relationship is protted in Fig. 4 using the results of the converse piezoelectric effect measurement Both figures show that the linear relationship exists between polarization and stress or between strain and electric field. This is an evidence that the effect is truely piezoelectric and not electrostrictive. The electrostriction can be observed in every materials but in this effect the strain is proportional to the square of the applied electric field.

The measured values of piezoelectric constant of bone in the case of (1) and (2) in Fig. 1 are represented in Table I. Lower values in the static piezoelectric measurement may be due to the leakage at the specimen and the measuring apparatus.

Table I. Piezoelectric constant of bone of man. (c.g.s. e.s.u.)

	direct effect		converse effect
	static	dynamic	dynamic
(1)	2.0×10^{-9}	2.9×10^{-9}	2.9×10^{-9}
(2)	2.2×10^{-9}	3.6×10^{-9}	3.5×10^{-9}

The specimens cut as shown in Fig. 1 have been examined in various ways of applying pressure. Silver foils were attached to the side planes as electrodes and the pressure was applied upon the other side planes or the square planes. The piezoelectric effect could not be observed in these cases.

The sign and magnitude of charge appeared on the square plane are very different according to the direction of pressure as shown (1), (2), (3) and (4) in Fig. 1. We take the piezoelectric constant of bone d_b as positive when the front square plane in the specimen in Fig. 1, that is, the outside plane of bone is positively polarized, as in the cases of (2) and (4). If we plot d_b against the angle between the bone axis and the direction of pressure, we obtain Fig. 5. The piezoelectric effect disappears when the direction of pressure makes the angle of about 10 degrees with the bone axis.

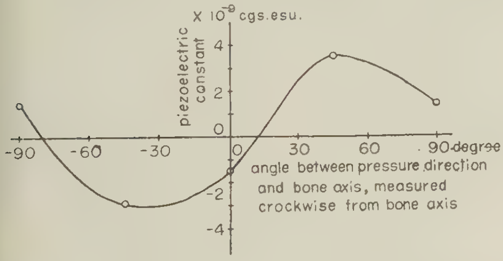

Fig. 5. Dependence of the piezoelectric constant of femur of man upon the angle between the pressure direction and the bone axis.

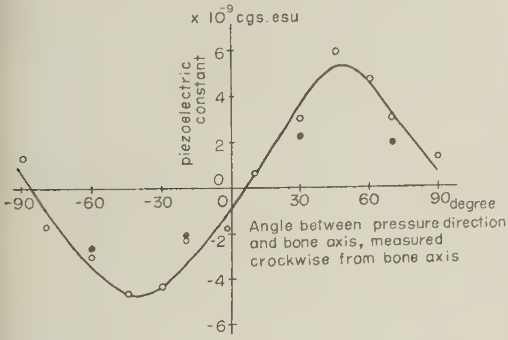

Fig. 6. Dependence of the piezoelectric constant of femur of ox upon the angle between the pressure direction and the bone axis.

The relation of d_b and the angle between the bone axis and the pressure direction were investigated more extensively using the bone of ox. Several pieces of plate were cut out from the femur of ox, which have different angles with the bone axis. The results are given in Fig. 6. The piezoelectric constants were determined by the measurement of the converse effect.

The similar curve as in Fig. 5 was obtained. The piezoelectric constant is zero at the angle of about 10 degrees, too. Black points show data when the specimen was first boiled in hot water for about 2 hours and afterwards dried completely by heating up to 120°C for about 5 hours. Little difference was observed between specimens boiled and unboiled, which ascertains that the effect is not entirely of biological origin.

Formerly Yasuda has observed that the piezoelectric effect still remains after the immersion of human bone specimen in acid for three weeks, so that the apatite crystals lying between the collagen fibres has completely dissolved.

The highest value of piezoelectric constant in the bone of ox is 6×10^{-9} c.g.s. e.s.u., which is about one-tenth of the piezoelectric constant d_{11} of quartz crystal.

§ 5. Discussions

From the above described experimental results we can conclude that the bone manifests the piezoelectric effect similar to that of the crystalline materials. The value of the piezoelectric constant amounts to about one-tenth of that of quartz.

In general the anisotropic crystals have the piezoelectric effect and their piezoelectric constants can be represented by the following matrix[8]:

$$\begin{pmatrix} d_{11} & d_{12} & d_{13} & d_{14} & d_{15} & d_{16} \\ d_{21} & d_{22} & d_{23} & d_{24} & d_{25} & d_{26} \\ d_{31} & d_{32} & d_{33} & d_{34} & d_{35} & d_{36} \end{pmatrix}$$

In the case of bone, the piezoelectricity appears only when the shearing force acts on the orientated collagen fibres so that they slip past one another. Considering the present results of experiments we can deduce the matrix of piezoelectric constant in this case as follows;

$$\begin{pmatrix} 0 & 0 & 0 & d_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & -d_{14} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

if the symmetry axis Z is inclined about 10 degrees to the right side from the bone axis. This matrix is quite the same as that of wood and ramie bundle.

The crystalline structure of collagen fibres has been well investigated. For example, Romachandran and Kartha[9] have proposed the hexagonal symmetry in the unit cell of collagen. The matrix of piezoelectric constant of crystal possessing hexagonal symmetry D_6 is represented by the same formula as described obove.

The microscopic structure of bone consists of the thin layers of spirals of collagen fibrils which are alternatively turned to the right and to the left. The crystallites of collagen are highly orientated in the direction of the axis of fibrils. The consideration of the symmetry of this system shows us that the above mentioned matrix of piezoelectric constant holds good, except that the value of d_{14} in the total system is lower than that of single crystal of collagen molecules. Even if the symmetry of the collagen micelle is not hexagonal, for example, monoclinic or rhombic, the matrix of the total system is also represented by the same formula.

It is noticeable that the Z axis assigned in this matrix is inclined about 10 degrees to the long axis of bone of femur. The x-ray diffraction patterns of the specimen has also shown the inclination of symmetry axis to the bone axis. We suppose that it might be caused by the fact that the bone axis of femur is not vertical when man or ox is in the standing position, so that the bone axis is slightly inclined to the direction of gravitational force, in which the resultant axis of collagen fibrils lies. If the bone of leg (tibia), where the bone axis is in the same direction as the gravitational force, is examined, then the Z axis in the piezoelectric matrix might coincide with the bone axis. More extensive studies using specimens which are cut out in various directions and different positions seem to be necessary.

Photoelectric Emission of Oxide Coated Cathodes

By Tadaichi YABUMOTO and Syôzi YAMADA

Institute of Electronic Engineering, Shizuoka University, Hamamatsu, Japan

(Received August 7, 1957)

The spectral sensitivity of photoelectric emission current from barium strontium oxide coated cathodes has been studied at room temperature. Under some conditions a new peak of the sensitivity curve was found at about 4.7 ev in incident photon energy.

This peak was observed on the cathode to which a small amount of oxygen gas was added. Fig. 1 is an example of the cases, where the curves were obtained from the cathode after being exposed to oxygen atmosphere of 10^{-5}–10^{-6} mmHg for about five minutes. This peak disappeared, when the cathode was heated at about 700°K, or was exposed to oxygen atmosphere of 10^{-4}–10^{-5} mmHg as shown in the figure. These phenomena are reproducible provided the chathode is aged in vacuum or electrolytically activated. During both activation processes the gas pressure in the tube was found to increase to 10^{-6}–10^{-7} mmHg, and it may be attributed to the releasing of oxygen from the cathode.

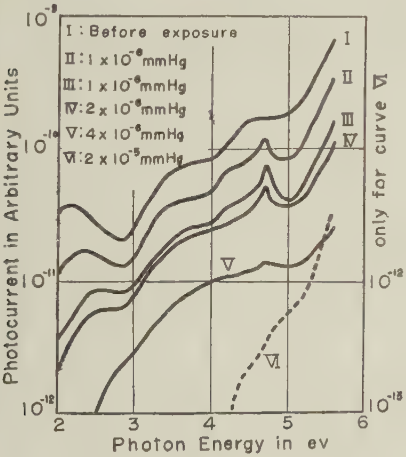

Fig. 1. Spectral sensitivity of photoemission after oxygen exposure.

If batalum getter near the cathode was heated in short duration after an appropriate aging process, it was found that the peak at 4.7 ev initially increased and then gradually diminished. Thereafter no peak appeared by successive heating of the getter. The results are shown in Fig. 2. These facts suggest that the peak is not attributed to barium but to other material initially evaporated from the getter. (probably oxygen).

Accordingly, it seems that the source of this peak is closely connected to oxygen added on the cathode. Since optical activation energy from the top of the filled band to the vacuum level has been known to be about 5.0 ev in BaO[1], the energy level corresponding to the oxygen will be situated at about 0.3 ev above the top of the filled band.

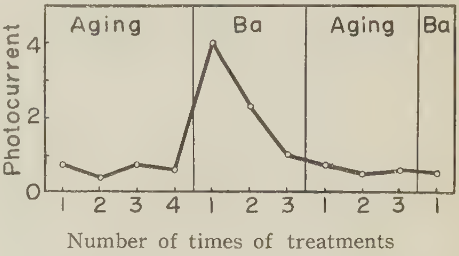

Fig. 2. Variation of photoelectric sensitivity peak at 4.7 ev with aging of the cathode and heating of a batalum getter.

It may be either the surface level due to adsorption of oxygen or the acceptor level. Though it is not clear at present which is the case, the levels are probably localized at the surface region of the oxide from the following reasons: 1) photon absorption coefficient is so large at these high energy region[2] that these photons cannot penetrate into the bulk, 2) the peak easily disappears by heating the cathode (diffusion or evaporation of the centers), 3) at room temperature the peak appears by oxygen exposure and disappears after a long time and 4) the magnitude of this peak is closely connected to the oxygen pressure in the experimental tube before the measurements.

The Galvanomagnetic Effects in Single Crystal of PbTe

By Kisaburo SHOGENJI and Susumu UCHIYAMA
Department of Electrical Engineering, Faculty of Engineering, Nagoya University, Nagoya

(Received July 18, 1957)

Measurements of the magnetoresistance of single crystal of semiconductor give an important information of its band structure.[1][2] Here we report measurements of the magnetoresistance effect and also the planar Hall effect[3] in synthetic p-type

Curve	Current	ax. of rot.
1	[100]	[010]
2	[110]	[1̄10]

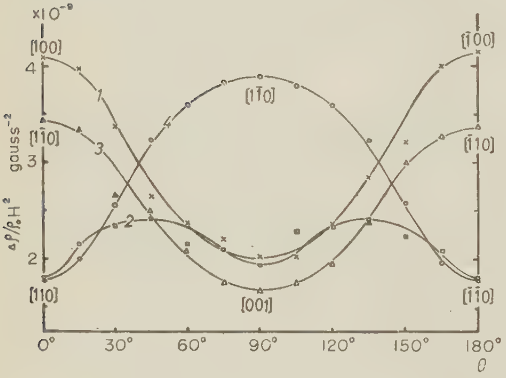

Fig. 1.

single crystal of PbTe. The measurements were made for two specimens, one of which had its long axis in [100] direction and the other in [110] direction; they were cut from the same ingot whose Hall coefficient was $+2.48\, cm^3/coul.$ and resistivity $1.93\times10^{-1}\,\Omega\, cm$ at 90° K, their temperature d pendence being normal.

The measured results at 90°K and with 80 gauss are shown in Figs. 1 and 2. In Fig. 1 vari tion of the magnetoresistance with respect to angle between the electrical current and the magn tic field, is shown with the direction of curren and the axis of rotation as it is measured. T

Curve	Current	ax. of rot.
I	[100]	[001]
II	[110]	[001]

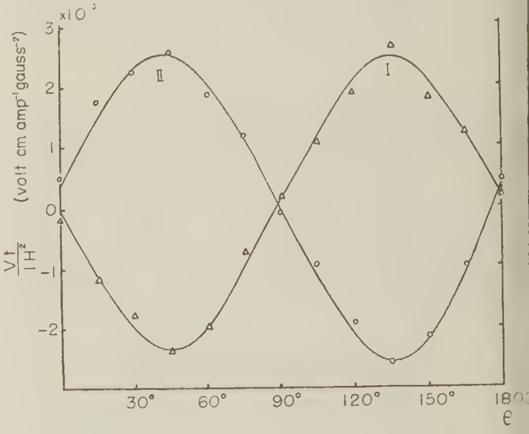

Fig. 2.

planar Hall effect is shown in Fig. 2 and its vari ation with regard to angle is sinusoidal as expecte from the theory.[3] The field dependence of th magnetoresistance and the planar Hall voltage i approximately expressed as the square of the fiel up to 10000 gauss in all cases: exactly speaking however, their exponent with respect to field i a slightly smaller than two. The relation $\Delta\rho/\rho_0 H$ *vs.* θ does not necessarily conform to Seitz' theory.[4] The behaviour of curve *2*, which deviate appreciably from curve expected theoretically, tell us an appearance of terms of higer order i magnetoresistance, *i.e.* terms proportional to H^4.

From magnetoresistance						From planar effect	
$b\times10^9$	$c\times10_6$	$d\times10^9$	$\beta\times10^5$	$\gamma\times10^5$	$\delta\times10^5$	$c\times10^9$	$d\times10^9$
2.00	−2.16	4.20	−9.60	9.68	−2.18	−2.59	5.29

The constants[1] of magnetoresistance obtained are shown in Table, which represent the data plotted in Fig. 1 fairly well except curve *2*. In Table the values of c and d which are obtained from planar Hall effect[3] are also shown; Their values are satisfactorily in accordance with those obtained from the magnetoresistance.

When the results are interpreted according to Shibuya's theory,[2] p-type PbTe may be concluded to have spheroidal energy surfaces with their extrema along [111] and its equivalent axes, since the values of $\beta+\gamma+\delta$ and $\beta+\gamma-\delta$ are far apart fro zero as compared to the value $\beta+\gamma$, and $\delta<0$.

The authors wish to thank Professor Y. Sakak for his kind guidance in carring out this research

Magnetic Properties of $NiTiO_3$–Fe_2O_3 Solid Solution Series

By Yoshikazu Ishikawa

Institute of Science and Technology,
University of Tokyo, Tokyo

(Received June 18, 1957)

Hitherto, the magnetic properties of solid solu- ions of ilmenite ($FeTiO_3$) and hematite (Fe_2O_3) have been studied in detail.1)2) They are entirely new type of ferromagnetics and other ferromagne- ic compounds which belong to this type have not yet been found. In these studies, it was supposed hat the complicated magnetic properties of these materials would be partially due to unstableness of $FeTiO_3$ at high temperature.

We have reported in the previous paper3) that $NiTiO_3$ is a stable compound having the same crystal structure as $FeTiO_3$. If, therefore, the magnetic properties of the solid solutions of $FeTiO_3$ and Fe_2O_3 has its origin in their crystal structure, we could expect the same situation for the solid solutions between $NiTiO_3$ and Fe_2O_3. To examine this idea, we have prepared the solid solution of $NiTiO_3$ and Fe_2O_3 and investigated their magnetic properties.

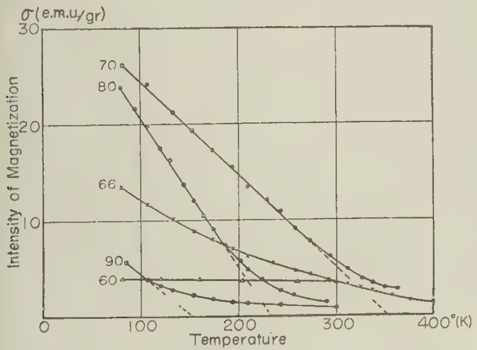

Fig. 1. The intensity of magnetization for a field of 8350 Oe vs. temperature. The numbers in the figure indicate mole percentages of $NiTiO_3$ in the compounds.

In this paper we report the outline of our results. t was found by X-ray analysis that $NiTiO_3$ and Fe_2O_3 can make the solid solutions over the whole range of composition. Their magnetizations were measured down to the liquid nitrogen temperature n a field of 8350 Oe as shown in Fig. 1. The numbers in the figure indicate the mole percentages of $NiTiO_3$ in the solid solutions. As is seen in the igure, the specimens become strongly ferromagne- ic only in a limited region of composition just ike the solid solution of $FeTiO_3$ and Fe_2O_3; that s, x $NiTO_3$—$(1-x)$ Fe_2O_3 seems to be ferromagnetic only for $0.9 \geqq x > 0.6$. The thermomagnetic curves are quite similiar to those of solid solutions of $FeTiO_3$ and Fe_2O_3. Besides, the circumstance that the magnetization is largest for $x \simeq 0.7$ is also same as that for the case of $FeTiO_3$ series.

As all specimens prepared contain a trace of impurities of the ferromagnetic spinels, the Curie temperatures of antiferromagnetic specimens ($x \leqq 0.6$) can not be determined from this experiment. For ferromagnetic specimens ($x > 0.6$), however, we can estimate them from the figure. The changing rate of the Curie temperatures with composition seems to be same as that of $FeTiO_3$ series.

The magnetic susceptibilities of this solid solutions were found to obey the Curie-Weiss law at high temperature. In Fig. 2 C_m and Θ obtained from the formula $\chi_m = C_m/T+\Theta$ are plotted against composition. We find that they vary almost linearly with composition. This is not the case for $FeTiO_3$ series, for which the anomalous dependences of C_m and Θ upon composition are observed for the ferromagnetic specimens.

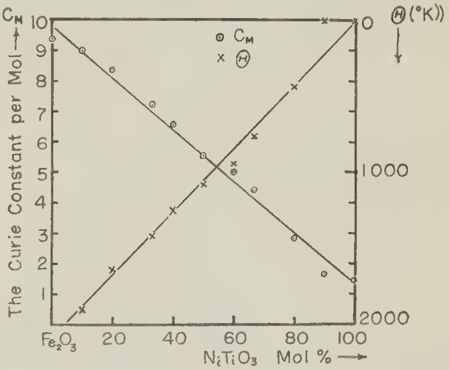

Fig. 2. C_m and Θ obtained from the Curie-Weiss law $\chi_m = C_m/T+\Theta$ vs. the composition.

Another marked difference is as follows: For $NiTiO_3$ series the magnetization of the specimen for $x=0.6$ is very weak, while for $FeTiO_3$ series the specimen of 0.6 $FeTiO_3$–0.4 Fe_2O_3 is strongly ferromagnetic. We may suppose that such differences are to some extent attributed to the following situation. In the case of $FeTiO_3$ series, the conductivity being relatively high, the ordering of Fe^{+2} and Fe^{+3} ions can occur merely by the electron transfer. In the case of $NiTiO_3$ series, on the other hand, Ni^{+2} and Fe^{+3} ions are fixed to lattice sites at the time of preparation of specimen.

The auther withes express his sincere thankes to Prof. Shozo Sawada for his encouragement throughout this investigation.

Iodine Quadrupole Resonances in ICl_3 and AlI_3

By Shigeo Hagiwara, Kiyoe Kato, Yoshihito Abe and Midori Minematsu

Department of Physics, Tokyo University of Education

(Received July 31, 1957)

Nuclear quadrupole resonances of I^{127} have been measured in solid iodine trichloride and aluminium triiodide with superregenerative spectrometers. A sample of iodine trichloride was produced by adding iodine into liquid chrorine. Aluminium triiodide was produced by direct interaction between aluminium and iodine. The high frequency lines of ICl_3 were detected with the cavity-type spectrometer[1] and other lines with the transmission type spectrometers[2]. The obtained results are listed in Table I.

The frequencies of two resonance lines in Al were measured simultaneously to get rid of th change of temperature of sample[3]. The structu of solid ICl_3 is considered as built up of plan I_2Cl_6 molecules, which consist of ICl_4^- and ICl_2^+ The obtained coupling constant of ICl_3 is very nea the value of ICl, 3008.3 Mc[4] at 20°C. Therefor the observed resonance is probably arisen fro ICl_2^+. Because of filled *p* orbitals the iodine n cleus in ICl_4^- seemes to give rise to no resonance The chlorine resonances in ICl_3 was first studie by Bray[6]. He reported two resonance lines a liquid nitrogen temperatures. We have also mea sured the lines at 31°C and obtained the frequen cies of 34.87 Mc and 33.39 Mc, which agreed we with Bray's value taking into account temperatu effect. If the molecule had a resonance structu as the case of AlI_3 three resonance line should b detected. However, only two resonance were ob served.

Table I. Nuclear Quadrupole Resonance of I^{127}.

sample	T(°C)		ν_1 (Mc)	ν_2 (Mc)	η (%)	eQq (Mc)

* S. L. Segel and R. G. Barnes: J. Chem. Phys. **25** (1956) 578.

The three resonance lines of I^{127} in AlI_3 was already studied by Segel and Barnes[7]. They suggested the indirect spin-spin interaction from their results that the ratio ν_3/ν_1 was slightly greater than two and the lines were broad having line width of about 50 kc. In the present experiment the lower resonance frequencies ν_1's are in agreement with their values. The higher resonance frequencies ν_2's, however, are lower than their values by about 500 kc. As a result the ν_2/ν_1 become smaller than two and yielded real value of asymmetry parameter. The line width of the higher frequency lines was observed as 40 kc. But the lower frequency lines were not so broad and had a line width of about 10 kc∼14 kc. Therefore, large indirect spin-spin interaction as the case of iodine is not expected.

On the Dielectric Properties of α-phase n-Higher Alcohols and Associated Electromotive Force

By Mikio Takeyama

Department of Physics, Faculty of Science, Hiroshima, University

(Received April 18, 1957)

The author has measured ε' and ε'' of n-higher alcohols in the frequency-range from several hundreds cycles to kMc (λ=1.2 cm.) and observed that, in α-phase, a dielectric dispersion occurs in microwave region as well as in low frequency region. The frequency dependence of ε' and ε'' of octadecyl alcohol, $C_{18}H_{37}OH$, is given in Fig. 1. A similar curve has been obtained for tetradecyl alcohol, $C_{14}H_{29}OH$. But for cetyl alcohol, $C_{16}H_{33}OH$, two peaks have not been clearly separated, though it is certain that a dielectric dispersion occurs in microwave region.

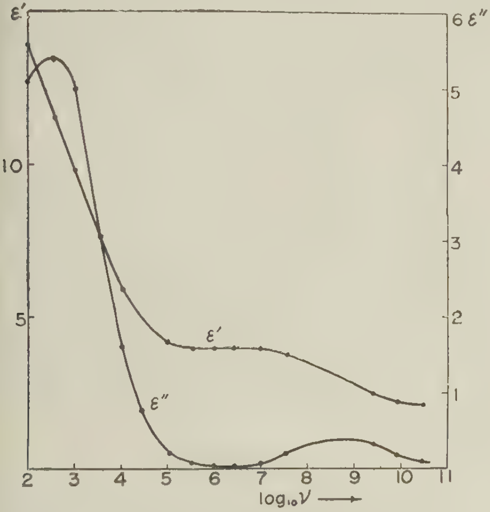

Fig. 1. Frequency dependence of dielectric constant of octadecyl alcohol (in α-phase).

It seems reasonable to consider that such a dispersion in microwave region is due to a certain degree of freedom of OH-radicals of those alcohols.

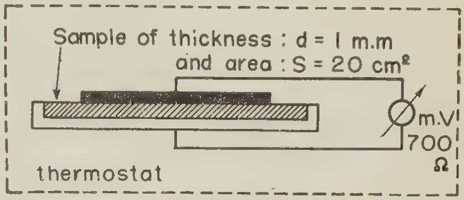

Fig. 2.

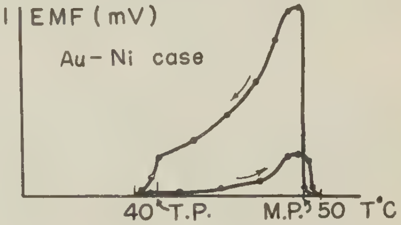

Fig. 3. Temperature dependency of the electromotive force of cetyl alcohol.

On the other hand, sample pieces of α-phase placed, as shown in Fig. 2, between two metallic plates of different kinds (for example, Pt and Ni) give rise to such electromotive forces as given in Table I. The temperature dependence of the electromotive force is represented by the curve given in Fig. 3. Such an electromotive force appears neither in β-phase nor in liquid state. It should be noted that the form of this curve is very much alike with that of the temperature dependence of ε' and ε'' of this sample and the electromotive orce is closely related to the work functions of he two metals, as one can see in Table I.

Table I.

Plates and polarity ⊕	⊖	Work function difference (eV)	Electromotive force (mV) max. value $C_{16}H_{33}OH$	$C_{18}H_{37}OH$
Pt —	Ni	5.3−4.6=0.7	2.1±0.2	
Pt —	Au	5.3−4.9=0.4	1.2±0.2	
Au —	Ni	4.9−4.6=0.3	1.0±0.1	0.3±0.1
Au —	Au	4.9−4.9=0	0	0

One may get a hint from this fact, as to explaining the proton transfer mechanism[1,2,3] of those lcohols which has been discussed by many workers.

The detailed report and discussion on the experimental results is to be published in "Journal of Science of Hiroshima University (Series **A**)". The samples used in this experiment were chemicals of Eastman Kodak Company.

In conclusion, the author wishes to express his sincere thanks to Prof. I. Takahashi of Kyoto University and Prof. H. Takeyama for their encouragement and useful advices.

Antiferromagnetic Resonance in $CuCl_2 \cdot 2D_2O$

By Muneyuki DATE

Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai, Japan

(Received July 25, 1957)

We have performed the experiments of the antiferromagnetic resonance in $CuCl_2 \cdot 2D_2O$ at 16100 Mc/sec of which the main purpose is to find out any slight difference of the antiferromagnetic properties of $CuCl_2 \cdot 2D_2O$ from that of $CuCl_2 \cdot 2H_2O$ which was previously investigated in detailed by the Leiden group.[1]

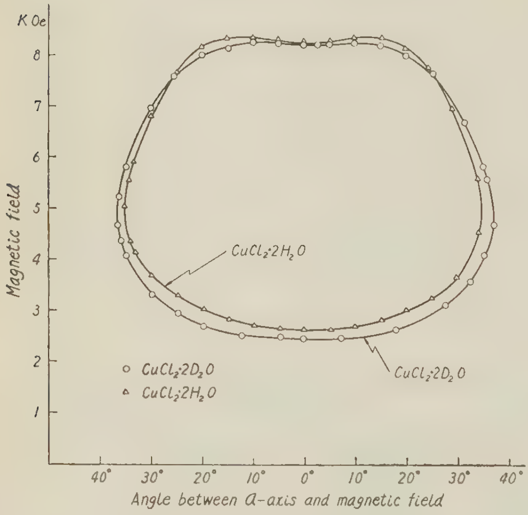

Fig. 1. Antiferromagnetic resonance in $CuCl_2 \cdot 2D_2O$ and $CuCl_2 \cdot 2H_2O$ in the *ab*.plane at 1.4°K.

The single crystal of $CuCl_2 \cdot 2D_2O$ was crystalized from saturated solution which contained 10 gr. D_2O as the solvent. The colour of the crystal is bright blue being slightly lighter than that of $CuCl_2 \cdot 2H_2O$. The size of the crystal used is of about 0.5 mm and the static magnetic field was applied in the *ab*-plane. The microwave circuit is usual one o the transmission type and the second harmonics o 2K25 klystron was used for the experiments. Special care was taken for the precise compariso of the results on $CuCl_2 \cdot 2D_2O$ and $CuCl_2 \cdot 2H_2O$ crystals. To avoid any slight difference in the experimental condition day by day, both crystal were mounted together but with orientations dif fering from each other and experiments were repeated for both crystals.

The experimental result are shown in Fig. 1 and may be summarized as follows :

1) The resonance constant C_1 in Nagamiya' theory[2] of the antiferromagnetic resonance is the same in both crystals within the experimental error

2) The resonance line of the low field branc at $a//H$ in $CuCl_2 \cdot 2D_2O$ is lower than that o $CuCl_2 \cdot 2H_2O$ and this means, according to the present theory of the antiferromagnetic resonance the smaller value of the other resonance constan C_2 of $CuCl_2 \cdot 2D_2O$ compared with that of $CuCl_2 \cdot 2H_2O$.

3) The dip appeared in $CuCl_2 \cdot 2H_2O$ at the top of the circle (Fig. 1) is reduced in $CuCl_2 \cdot 2D_2O$.

4) The total angle range in which the resonance can be observed in the *ab*-plane is 74° in $CuCl_2 \cdot 2D_2O$ whereas it is 70°30′ in the $CuCl_2 \cdot 2H_2O$.

The detailed account of the results and discussions will be published later. Finally the author wishes to express his cordial thanks to Prof. T Fukuroi for the stimulations during the course o the present research.

Galvanomagnetic Effects in n-type Indium Antimonide at Very Low Temperatures*

By Yasuo KANAI

Electrical Communication Laboratory, Musashinoshi, Tokyo

and Wataru SASAKI

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received June 25, 1957)

Recently, anomalous (oscillatory) galvanomagnetic effects in n-type Indium Antimonide (InSb) at liquid helium temperatures were found independently in the work done by Frederikse and Hosler[1] and in ours.[2] To obtain the more complete informations about these anomalous effects, we measured the galvanomagnetic effects of the single crystals of tellulium doped n-type InSb, which had the different electron densities and crystal orientations.

In Table I, the values of resistivity (ρ) and Hall coefficient (R) of our samples at various temperatures are listed. The ratio of the Hall coefficient R in the various magnetic field H to the value of R, $R_{10,000}$, in the magnetic field of 10 kG are shown in Fig. 1 as a function of the inverse value of the magnetic field. And it seems to us that these curves in Fig. 1 show the existence of the anomalous (oscillatory) Hall effect in the n-type InSb at very low temperatures.

Table I. The values of resistivity (ρ) and Hall coefficient (R) at various temperatures. In the all cases of Hall measurements, magnetic field was applied in the 001-direction.

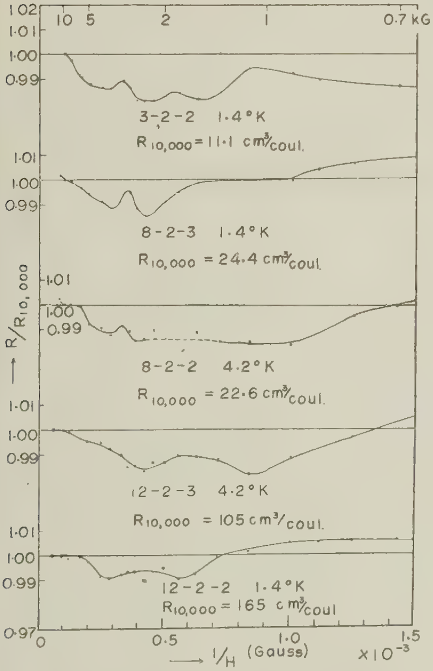

Fig. 1. The ratio of the Hall coefficient R at various magnetic field to the value of R, $R_{10,000}$, in the magnetic field of 10 kG as a function of the inverse magnetic field.

Corresponding to the anomaly in the Hall coefficient, the magnetoresistance of our samples also showed the same anomaly (oscillation) at very low temperatures. Unfortunately, however, it was found that the magnetoresistance of the n-type InSb was usualy depend on the shape of the sample, the absolute value of this effect was quite erroneous.

The authors are grateful to Prof. T. Fukuroi and his corworkers for the hospitality given in using the helium apparatus at the Research Institute for Iron, Steel and Other Metals of Tohoku University, and also to Mr. R. Nii and Miss C. Yamanouchi for their assistances in this work.

Nuclear Interactions in Nucleon-Proton and Nucleon-Carbon Nucleus Collisions above 10 GeV

By Koichi SUGA

Institute for Nuclear Study, University of Tokyo, Tanashimachi, Kitatamagun, Tokyo

(Received May 14, 1957)

Nuclear interactions in hydrogen and carbon by nucleon (a few to several tens of GeV) have been studied using a multiplate cloud chamber which contained paraffin, carbon and lead at mountain altitude. The cross-section for the nuclear interaction by nucleon-proton collision was found to be 60±17 mb, assuming the cross-section for nucleon-carbon nucleus 320 mb. Energy spectra of neutral pions produced in paraffin, graphite and lead were compared. The energy distribution of neutral pions in paraffin-interactions is more steep in low energy region and similar in high energy region compared with that in carbon-interactions, and possible interpretation will be given. Charged secondary particles are emitted isotropically in c.m. system in nucleon-nucleon collision, and in the carbon nucleus some secondary particles undergo secondary collisions in the same nucleus. The azimuthal angle distribution of secondary particles was examined and some comments will be mentioned.

§1. Introduction

Results of an experiment on penetrating showers from hydrogen and carbon will be reported. The experiment was carried out at Mt. Norikura Cosmic-Ray Laboratory, University of Tokyo (2840 m altitude), from summer to winter of 1955. This work is the continuation of previous studies[1] by CH_2–C subtraction method with a counter hodoscope. Main purposes of the present experiment are as follows: (I) To check results of the previous experiment (the cross-section of meson-production in hydrogen) with newly designed experimental arrangement. Ambiguities of the results caused by secondary interactions in the producer and the uncertainty of identifying the penetrating shower with a counter hodoscope were overcome by using a multiplate cloud chamber which contained thin producers of paraffin and carbon. (II) To obtain informations about neutral pions produced in hydrogen and carbon, using lead sheets in a cloud chamber. (III) To study the angular distribution of shower particles in the nuclear interaction.

§2. Experimental Arrangement

A sketch of the apparatus is shown in Fig. 1. The whole apparatus consisted of a hodoscope of G.M. counters and a multiplate cloud chamber which contained paraffin, graphite and lead sheets. The cloud chamber is of rear-illumination and lateral-expansion type, and was filled with 85 cm Hg argon and saturated vapor of ethyl alcohol. The illuminated region is about 50 cm×50 cm×40 cm. The chamber contained four layers of paraffin and graphite and three layers of the lead sheet of 1 cm thickness. Thickness of each layer of paraffin and graphite was made to 3.14 g/cm^2 and 2.68 g/cm^2, respectively, so that the both contained the same number of carbon nuclei. It is perhaps desirable that appearances of paraffin and graphite layers are made indistinguishable from each other, so that the personal bias is prevented which come into the visual inspection of cloud chamber photographs. Each graphite layer was composed of two slices piled up with spacers, and was covered with aluminium-foil of 50 microns thickness same as in the case of paraffin layer. Thus apparent thicknesses (of 3.5 cm) and appearances of paraffin and graphite were made to be very similar with each other. In order to reduce the effect from the difference of the detection-efficiency of nuclear interactions in paraffin and graphite by the counter coincidence system, each layer of paraffin and graphite (23 cm×41 cm) was set as shown in Fig. 1. In the course of the experiment, positions of paraffin and graphite were frequently interchanged.

There were four trays of G. M. counters

called *A*, *S*, *B* and *C*, respectively. Tray *S* consisted of 21 counters of 36 cm length and 2 cm diameter. Tray *A* and *B* contained 14 counters of 40 cm length and 4 cm diameter. Tray *C* was a group of 17 counters of 50 cm length and 4 cm diameter. Tray *B* was separated from Tray *S* by 15 cm of lead and 4 cm of iron. Each counter of this tray was wrapped by a lead sheet of 3 mm in thickness to reduce the effect of knock-on electrons. Tray *C* was separated from *B* by 5 cm lead. All counters of these trays were connected to each corresponding neon lamp through each hodoscope circuit.

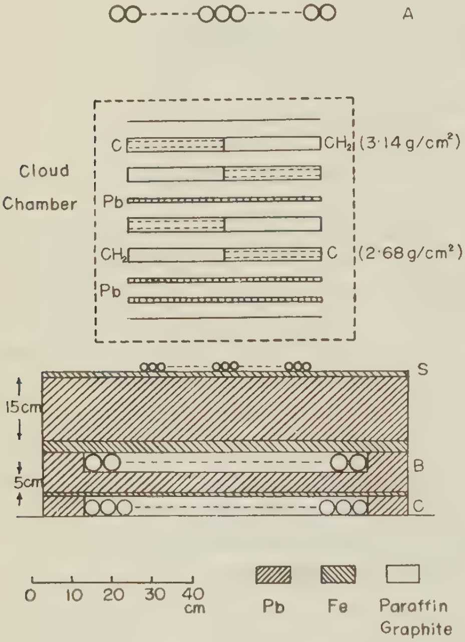

Fig. 1. A Sketch of the experimental arrangement.

The condition for a master pulse was simultaneous discharges of at least two counters of tray *S* and discharges of at least three counters in tray *B* and at least one counter in tray *C*. Photographs of the cloud chamber by two 35 mm cameras and photographs of the hodoscope by 16 mm cine-camera were taken with these master pulses. Experimental conditions of the cloud chamber were tested by visual inspection and electronic circuits were checked a few times per day.

§3. Analysis of Photographs

Cloud chamber photographs were taken with pieces of 35 mm films, each of which contained about 50 pictures. In order to avoid th personal bias in the course of visual inspectio of cloud chamber photographs, numbers o four orders which were obtained from th table of random number were attached t each piece of film before photography. Eac film was represented by these numbers. I the course of analysis, pieces of films wer mixed randomly and then the piece picked u was scanned. Photographs taken with th triggering master mentioned above show pene trating showers produced in paraffin, graphit or lead plate as well as air showers or som other spurious events. For the present study events which were produced in paraffin o graphite layers and were convincingly re garded as nuclear interactions were picke up and analysed stereoscopically. After th analysis, the assignment of events to paraffi (*P*) or graphite (*G*) was done with the aid o the number attached to each piece of film Criterion of the nuclear interaction was a follows: (1) event with one secondary partic which penetrates at least 2 cm of lead withou multiplication (penetrating particle) and one o more heavily ionizing particles and/or one o more cascade showers (2) with two or mor penetrating particles (3) with two or mor penetrating particles and one or more heavil ionizing particles and/or one or more cascad showers (4) with two or more cascade shower and/or heavily ionizing particles. Event which were produced in the region of 1 c from the edge of each producer were excluded because the uncertainty of determination o the position was about ±1 cm in this experiment.

§4. Results and Discussions

(1) Cross-Section for the Nuclear Interaction in Hydrogen

Scanning of all of photographs in this experiment has not yet been completed, 15 *P*-interactions and 120 *G*-interactions (produce in paraffin and graphite, respectively) wer obtained by both charged and neutral primar particles, after scanning and stereoscopic analysis of about a half of photographs along th procedure mentioned above. If the cross-section for nuclear interaction by nucleon-carbo nucleus collision is assumed, the cross-sectio for nucleon-proton collision can be obtaine from above rates of *P*- and *G*-interaction.

In order to inspect whether the ratio of rates of *P*- and *G*-interaction (*P/G*) is free from the personal bias and instrumental defects or not, distribution of *P/G* values was examined from the following points of view: (1) *P/G* values in the case of the different relative position of paraffin and graphite layers in the cloud chamber (2) *P/G* values at different height of producers in the cloud chamber (3) *P/G* values in producers in right and left sides in the chamber (4) *P/G* values in sequence of time in the course of scanning (5) *P/G* values in sequence of time in the course of the operation of the cloud chamber. The distribution of *P/G* values was consistent with that expected from the Poissonian fluctuation.

After the correction of the materials (Al-foil and adhesive material) that covered the producer, ratio $P/G=1.33\pm0.15$ was obtained. The energy of primary particles is considered to be a few to several tens of GeV as described in Section **4** (**3**) [**A**]. The cross-section for nuclear interaction by nucleon-carbon collision in this energy region is known to be about 320 mb by many authors[2)]. Then the cross-section for nucleon-proton collision is 53 ± 24 mb, because *P/G* ratio is equal to the value of (2×cross-section of proton + cross-section of carbon nucleus) divided by cross-section of carbon nucleus. This value is consistent with previously obtained cross-section in same energy region; that is 67 ± 25 mb. Taking weighted average of these two values, one obtains 60 ± 17 mb. This value is almost equal to the geometrical cross-section of 60 mb ($=\pi r_0^2$, $r_0=1.4\times10^{-13}$ cm), but is slightly higher than 42 mb at 2.75 GeV[3)] and 29.5 mb at 5.3 GeV[4)] obtained by the Cosmotron and Bevatron. Recently, E. Brenner and R. W. Williams[5)] obtained $\sigma=21$ mb for effective elementary nucleon-nucleon cross-section at 50 GeV from the cross-section for nucleon-iron nucleus collision; i.e. 615∼605 mb obtained experimentally. In our case, the cross-section for nucleon-proton collision is 49 ± 14 mb, even if we take 260 mb for the cross-section for nucleon-carbon nucleus collision which is the lowest value obtained up to present time in the energy region of a few to several tens of GeV.

As to the difference of the cross-section by proton and neutron primaries, none was observed, just as in the previous experiment.

(2) Production of Neutral Pions from Hydrogen and Carbon

Neutral pions produced in nucleon-proton and nucleon-carbon nucleus collisions were studied with the aid of cascade showers developed by the lead plates in the cloud chamber. In the present analysis, cascade showers which convincingly associate with nuclear interactions were examined, and cascade showers which have only one or two particles in only one space under a lead plate—namely cascade showers of very low energy—were excluded. No noticiable difference in multiplicity distribution and angular distribution between *P*-interactions and *G*-interactions was observed.

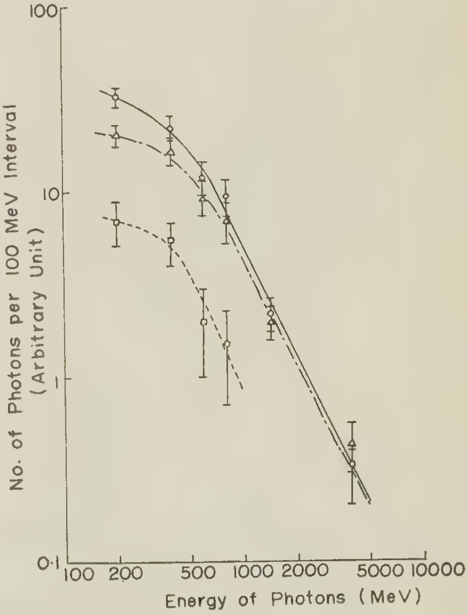

Fig. 2. Energy distribution of cascade showers produced in Paraffin (○), Graphite (△) and lead (□). The abscissa shows the energy of cascade showers in MeV, and the ordinate shows the number of cascade showers per 100 MeV interval in arbitrary unit.

The energy of cascade showers of *P*-interactions and *G*-interactions was estimated from the transition in three lead plates of 1 cm thick each, following the theoretical cascade curve by Snyder[6)7)]. It is preferable to use the correct curve by Monte Carlo Method, but it is not available up to several GeV. The energy distribution of cascade showers produced by the nuclear interaction in paraffin and carbon thus obtained is shown in Fig. 2, as well as one in lead. Because of missing some showers of low energy and of inaccuracy of the refered cascade curve, the absolute energy spectrum of cascade showers can not be shown, but the difference of energy distribution between paraffin and carbon may be discussed based on these results. In Fig. 2, the abscissa shows the energy of photons and the ordinate shows the number of photons observed for the same running time in paraffin and graphite and for rather small amounts of running time in lead in 100 MeV interval in arbitrary unit.

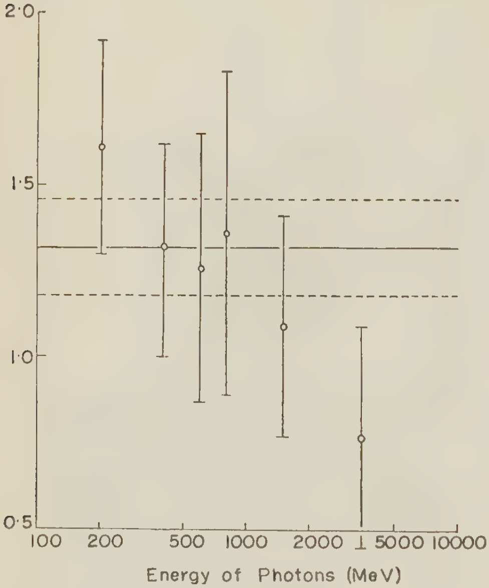

Fig. 3. Ratio of the number of photons produced in *P*- and *G*-interactions for the same running time vs. the energy of photons.

Although experimental errors are rather large, it may be seen that the energy distribution of photons in *P*-interactions is more steep in low energy region and similar in high energy region compared with that in *G*-interactions. And the energy distribution of photons in interactions in lead shows the same tendency as that of *G*-interaction. The ratio of numbers of the cascade shower in *P*- and *G*-interaction is shown in Fig. 3 with respect to the energy of photons. The full line and dotted lines show the ratio of the numbers of *P*-interaction and *G*-interaction and its statistical accuracy. From this figure, it may be seen that the ratio of the cascade shower for both interactions is rather high in low energy and rather low in high energy compared with the ratio of the number of both interactions These behavoirs might be due to the insufficient statistical accuracy, and the hasty conclusion is to be reserved. But those might be tentatively understood by the hypothesis that the production of charged pions of high energy is usual but that of neutral pions of high energy is rather less in the nucleon-nucleon collisions, and/or that neutral pions of low energy are absorbed by the successive collisions with nucleons in the same nucleus in carbon and lead.

(3) Angular Distribution of Charged Secondary Particles

In those interactions which contained cascade showers, charged secondary penetrating particles were often masked by these cascade showers. So, those 46 interactions which showed only charged secondaries and were caused by charged primaries were selected from 276 interactions produced in paraffin and graphite layers and were studied.

[A] *Colatitude-angle distribution of secondary particles*

Angles between the charged primary particle and each secondary penetrating particle were measured in each interaction and are named colatitude angles (θ). The colatitude-

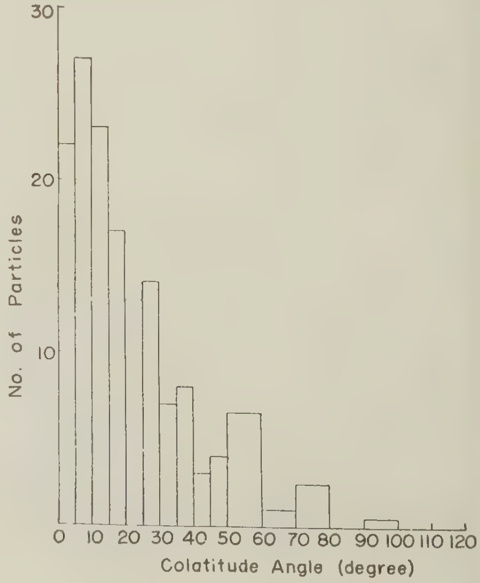

Fig. 4a) Colatitude-angular distribution of charged secondary particles in the laboratory system for total interactions.

angle distribution and the so-called F-plot[8] are shown in Fig. 4, including total events. F-plot is almost linear as is expected from the isotropic distribution and the approximate relation $m=\beta_c/\beta_\pi=1$ in the center-of-mass system in the nucleon-nucleon collision where β_c and β_π is the velocity of incident nucleon and produced pions in unit of the velocity of light, respectively. The tangent of the line, however, is not equal to 2, while it is expected so in the above condition. Further analysis, therefore, seemed to be necessary. Interactions were divided into three groups according to the mean colatitude-angle of each interaction (i.e. the primary energy or the Lorentz factor (γ_c) of primary particle—probably nucleon—in the c.m. system). Fig. 5 shows the distribution of mean colatitude-angle of each interaction and Table I shows the character of each group.

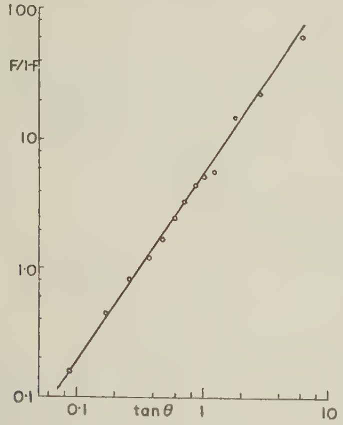

Fig. 4b) F-plot for the same data.

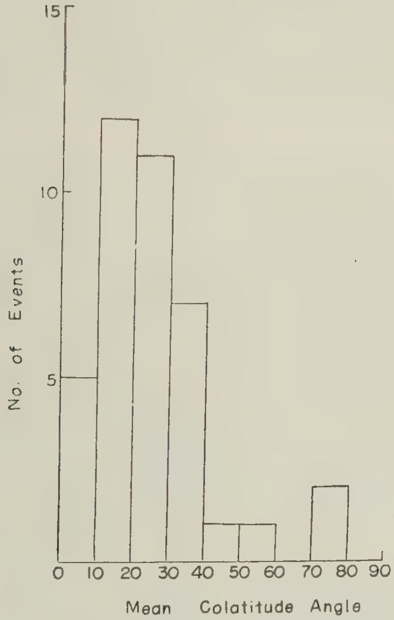

Fig. 5. Distribution of the mean colatitude-angle of each interaction in the laboratory system.

F-plots corresponding to each group are shown in Fig. 6, together with the F-plots corresponding to the case of smaller breadth of γ_c than Group I (Group I′) and to the case with at least 4 secondary particles (Group I″). Though errors are rather large, it may be seen from this figure that lines of Group I, I′ and I″ are almost linear but lines of Group II and III are curved. F-plots corresponding to the isotropic distribution with $m=1$, isotropic distribution with $m=1.03$, $\cos^2\theta$ distribution with $m=1$ and $\cos^2\theta$ distribution with $m=1$ and $\cos^2\theta$ distribution with $m=1.03$, in c.m. system assuming $\gamma_c=4$ are calculated and shown in Fig. 7, in order to examine what meanings those experimental F-plots show. From these curves and Fig. 6, it may be seen that Group I, I′ and I″ show nearly isotropic distribution with $m\approx1$ and Group II and III show rather sharp distribution in the forward and the backward directions with $m>1$ in c.m. system. And, also, Table I shows that the Group II and III have not less multiplicity than Group I irrespective of smaller value of $\bar{\gamma}_c$ than Group I and I′. These tendencies may

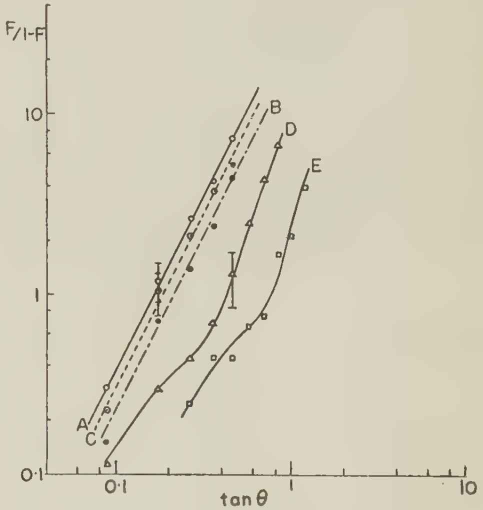

Fig. 6. F-plots for each group as shown in Table I. *A*: Group I, *B*: Group I′, *C*: Group I″, *D*: Group II and *E*: Group III.

Table I.

a) determined from the mean angle of secondary particles; $\gamma_c=1/\bar{\theta}$.
b) determined from F-plot, assuming the nucleon-nucleon collision.
c)d) determined from the shape of line in F-plot assuming the nucleon-nucleon collision.
d) $m=\beta_G/\beta_\pi$ in the center-of-mass system.
e) in this group, interactions with at least 4 secondary particles were selected.

be interpreted by the following hypothesis. The nucleon-nucleon collision and nucleon-nucleus collision without secondary interaction in the same nucleus show the isotropic distribution of secondary particles and have pions of high energy in c.m. system. But the nucleon-nucleus collision with secondary interactions will produce pions of rather low energy and shows rather sharp distribution in the forward and the backward directions, due to the analysis by the assumption of successive nucleon-nucleon collision, though each process of the nucleon-nucleon collision probably has the isotropic distribution. Under the above interpretation, the energy of primary particles may be a few to several tens of GeV from γ_c in Table I.

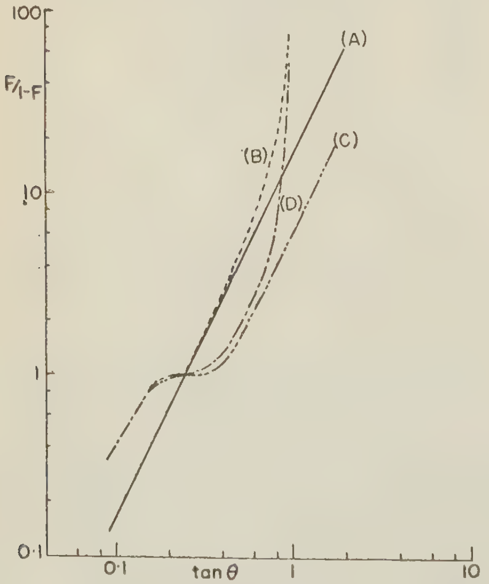

Fig. 7. F-plots for $\gamma_c=4$ calculated theoretically, assuming (*A*) isotropic distribution with $m=1$, (*B*) isotropic distribution with $m=1.03$, (*C*) $\cos^2\theta$ distribution with $m=1$ and (*D*) $\cos^2\theta$ distribution with $m=1.03$.

[B] *Azimuthal angle distribution of charged secondary particles*

Events examined in this section are the same as in the former section. The incoming direction of the primary particle was taken as *Z*-axis in the polar coordinate, and the so-called azimuthal angle (ψ) of the charged secondary particle was studied. The importance of the azimuthal angle distribution of secondary particles in the nucleon-nucleon collisions has been noticed from the view-point of the mechanism of the multiple production of mesons and especially from the possible role of the angular momentum of incoming nucleon to the multiple production of mesons.9) In this analysis, the arbitrary determination of origin in azimuthal angle is difficult and not adequte. So, the separation in the azimuthal angle between each secondary particle and its nearest neighbour was taken.

The separation angle is $\phi=\psi_{i+1}-\psi_i$, and $P(\phi)$ is the frequency of cases with angular separation ϕ. $W(\phi)=\int_{\phi}^{2\pi}P(\phi)d\phi \Big/ \int_{0}^{2\pi}P(\phi)d\phi$ vs. ϕ is shown in Fig. 8 (a) and (b) in interactions with three and six secondary particles respectively, together with same curves obtained by the Monte Carlo Method assuming the random and $\cos^2\psi$ distribution. In interactions with three secondary particles, decision whether the experimental distribution belongs to the random distribution or $\cos^2\psi$ distribution

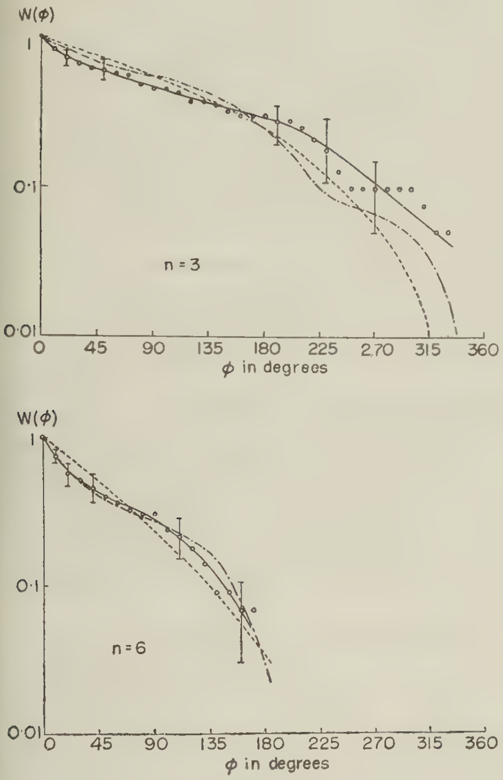

Fig. 8. Curves which shows the relation between

$$W(\phi)=\int_{\phi}^{2\pi}P(\phi)d\phi \Big/ \int_{0}^{2\pi}P(\phi)d\phi \text{ and } \phi.$$

(a): for interactions with 3 secondaries, (b) for interactions with 6 secondaries. Full line shows the experimental curve and dotted and dot-dashed curves show the curves obtained theoretically assuming the random and $\cos^2\psi$ distribution, respectively.

is very difficult, owing partly to the large statistical error and partly to the contribution of neutral secondary particles and effect of the momentum of secondary particles. But in interactions with six secondary particles, the observed curve is close to the curve expected from the $\cos^2\psi$ distribution. Any decisive conclusion is to be reserved in the present state of analysis. But considering the interpretation described in the preceding section that interactions with many secondary particles may undergo some secondary interactions, the $\cos^2\psi$ distribution may be due to the fact that a special secondary particle as a case of fluctuation collides with a nucleon in the same nucleus and produces some tertiary particles so that such particle may make some small angular separations ϕ in a special direction and the azimuthal angle distribution looks like $\cos^2\psi$ distribution as the result of the statistical accumulation of these cases along the present procedure of analysis. Nothing is concluded in the cases of nucleon-nucleon collisions, but these lines of analysis, perhaps, may be effective if data will be accumulated more.

Acknowledgment

The author wishes to express his sincere appreciation to Professor Yuzuru Watase for his very helpful discussions and advices. And he is also indebted to Mr. Y. Tanaka and Mr. S. Mitani for their skill and effort in construction of the equipment and co-operation in the course of the observation. Without their valuable assistances, this work could not be achieved. Also, the author is greatly indebted to Prof. I. Miura and Mr. G. Tanahashi who have informed their results before publication and gave valuable advices to the author, and to Prof. M. Oda who has read this article and given valuable criticism. This work was done when the author had been at Department of Physics, Faculty of Sience, Osaka University. And this work was partly financed by the Ministry of Education in Japan under the Fundamental Scientific Research Expenditure.

Gamma Rays from the Excited States of ^{16}O

By Tetsuo WAKATSUKI, Yasuo HIRAO, Eiji OKADA
and Iwao MIURA

Department of Physics and the Laboratory of Nuclear Studies,
Faculty of Science, Osaka University, Osaka

(Received July 30, 1957)

By bombarding fluorine target with 5.7 MeV protons, a new gamma radiation of energy 3.86±0.02 MeV was observed with a three crystal pair spectrometer. This gamma radiation was proved to be emitted from 10.98 MeV (or 10.77 MeV) state in ^{16}O in the transition to 7.12 MeV (or 6.91 MeV) state by gamma-gamma coincidence experiments. No gamma radiation corresponding to the transitions from this state to other lower states in ^{16}O was observed. 0^- (or 3^+) was assigned to this state.

An 8.87 MeV gamma radiation corresponding to the direct transition to the ground state from the 2^- excited state in ^{16}O was observed.

A hard gamma radiation of about 11 MeV energy was found at proton energies between 4.8 and 5.7 MeV and was ascribed to the capture radiation in ^{19}F$(p\gamma)^{20}$Ne reaction.

A weak gamma radiation of about 4.9 MeV energy was also observed.

§ 1. Introduction

Excited states of ^{16}O have been the objects of many experimental and theoretical investigations. Experimentally, the excited states of ^{16}O were observed chiefly in ^{19}F$(p, \alpha)^{16}$O*1)2)3)7), ^{16}O$(p, p')^{16}$O*1)4), ^{16}O$(n, n')^{16}$O*5) and ^{15}N$(d, n)^{16}$O*1)6)7) reactions or observed as the compound nucleus levels in ^{12}C$(\alpha, \alpha)^{12}$C8), ^{15}N$(p, \alpha)^{12}$C1)9) and ^{15}N$(p, n)^{15}$O1)10) reactions.

Dennison11) and Kamney12) have calculated the excited states of ^{16}O using alpha particle model and showed good correspondence between the theory and experiments. According to Kamney, of the first nineteen excited states which are experimentally observed (0–12.95 MeV), fourteen are definitely predicted, two levels (11.10 and 12.95 MeV) are observed but not predicted and three levels (8.87, 11.08 and 12.02 MeV) are tentatively predicted but await experimental determination of spins and parities. (Identification (a) of reference (12)).

To the first of these three excited states (8.87 MeV), 2^- was assigned in accordance with theoretical prediction by Wilkinson, Toppel and Alburger2) in the investigation of the gamma rays from ^{19}F$(p, \alpha)^{16}$O* reaction at proton energy of 3.7 MeV.

The spins and parities for 11.08 and 12.02 MeV states predicted by Kamney's theory are 3^+ and 1^+ respectively. But there are no experimental evidences for such assignments.

As the protons of energy up to 5.7 MeV are obtainable with our newly built cyclotron13), we undertook an examination of the higher excited states of ^{16}O using the same reaction ^{19}F$(p, \alpha)^{16}$O* as the above experiment

§ 2. Experimental Methods

Molecular ion beam of hydrogen accelerated by Osaka University 44 inch cyclotron was focussed onto a target located at about meters from the cyclotron by a wedge type focussing magnet through concrete shield wal of 1.5 meter thickness. The energy of the proton was estimated to be 5.7±0.1 MeV from the measurements of the range in air and in nuclear emulsion. To vary the energy of the incident proton, aluminium absorbers of different thicknesses were imposed at about one meter in front of the target. The beam defining slit was made of a gold plate with a circular hole two millimeters in diameter in gamma-gamma cascade experiment, but the diameter was increased to one centimeter in most other cases. The proton current was varied with the problem in hand from a few thousandths of a microampere up to about 0.5 microampere.

Teflon or BaF$_2$ targets of a few mg/cm thickness were bombarded by protons and the gamma rays were observed with scintillatio spectrometers.

We have used single crystal spectrometers with Harshaw NaI(Tl) crystal 1½ inch in diameter and 1½ inch in length. In a later work, a larger crystal 3 inches in diameter and 3 inches in length was emplyed. We have also used a three crystal pair spectrometer[14] with center crystal 1 inch in diameter and 2 inches in length. The energy resolution of the three crystal spectrometer for 4.43 MeV gamma ray was about 6%.

The time resolution of the coincidence circuit in the three crystal pair spectrometer and in gamma-gamma coincidence work was 0.1 microsecond. In gamma-gamma coincidence work, the "fast-slow coincidence" technique was used. The pulses from one crystal which were in coincidence with selectively chosen gamma rays detected by the other crystal were analysed.

To avoid the back ground gamma rays, scintillation spectrometers were surrounded by lead blocks ten centimeters in thickness.

For the measurements of pulse height distribution, Atomic Instrument Company 20-channel pulse height analyzer was used. The calibrations of the energies were performed by 2.75 and 6.13 MeV gamma rays produced in $^{19}F(p, \alpha\gamma)^{16}O$ reaction[2] and 4.43 MeV gamma rays produced in $^{12}C(pp'\gamma)^{12}C$ reaction[1]. As the monochromatic 4.43 MeV gamma ray is produced with high intensity when polyethylene is bombarded by protons, this gamma ray was used frequently as the reference line in the determination of gamma ray energies.

§ 3. Results and Discussions

Fig. 1 and Fig. 2 show the gamma ray spectrums observed with the three crystal spectrometer placed at right angle to the proton beam when BaF_2 and teflon were bombarded by 5.7 MeV protons. In addition to the well known gamma rays of 6.13, 6.91 and 7.12 MeV energy from the excited states of ^{16}O[1], 1.76, 1.96, 2.75, 3.86 and 4.9 MeV gamma rays are observed. The first three of them were shown by Wilkinson et al.[2] to come from the 8.87 MeV excited states of ^{16}O. In Fig. 2, the deexcitation gamma rays from the first excited state of ^{12}C (4.43 MeV) are also observed.

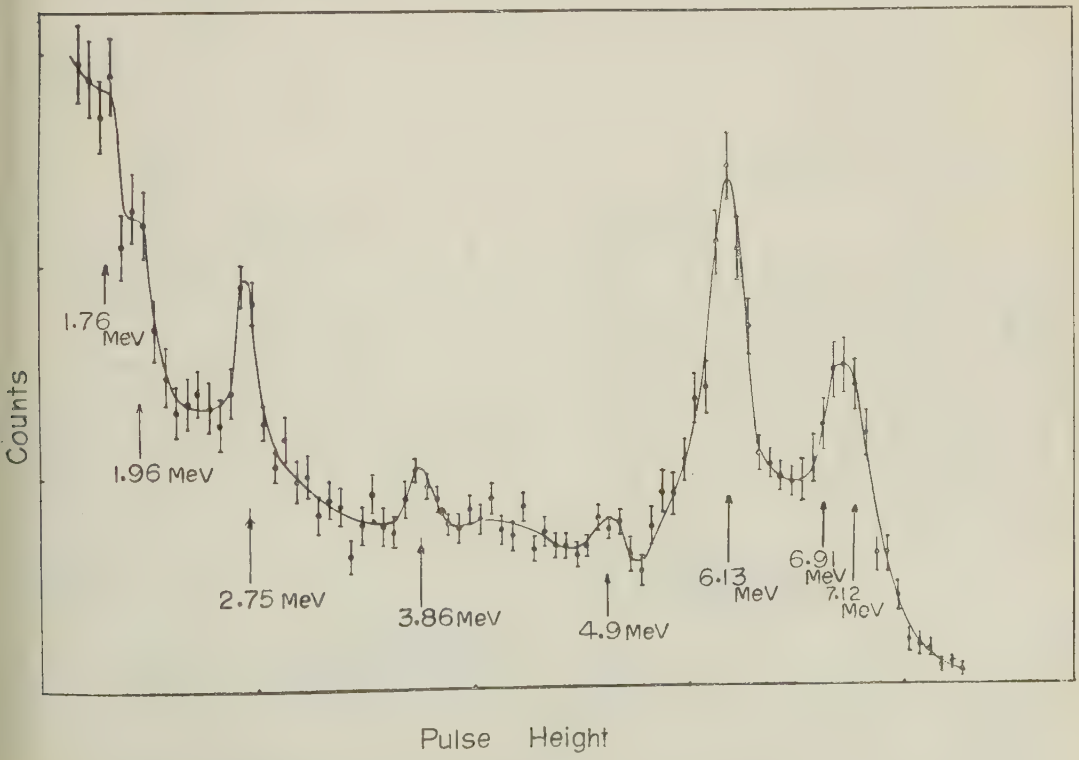

Fig. 1. Three-crystal pair spectrum; BaF_2+p at 5.7 MeV and 90° with respect to the proton beam.

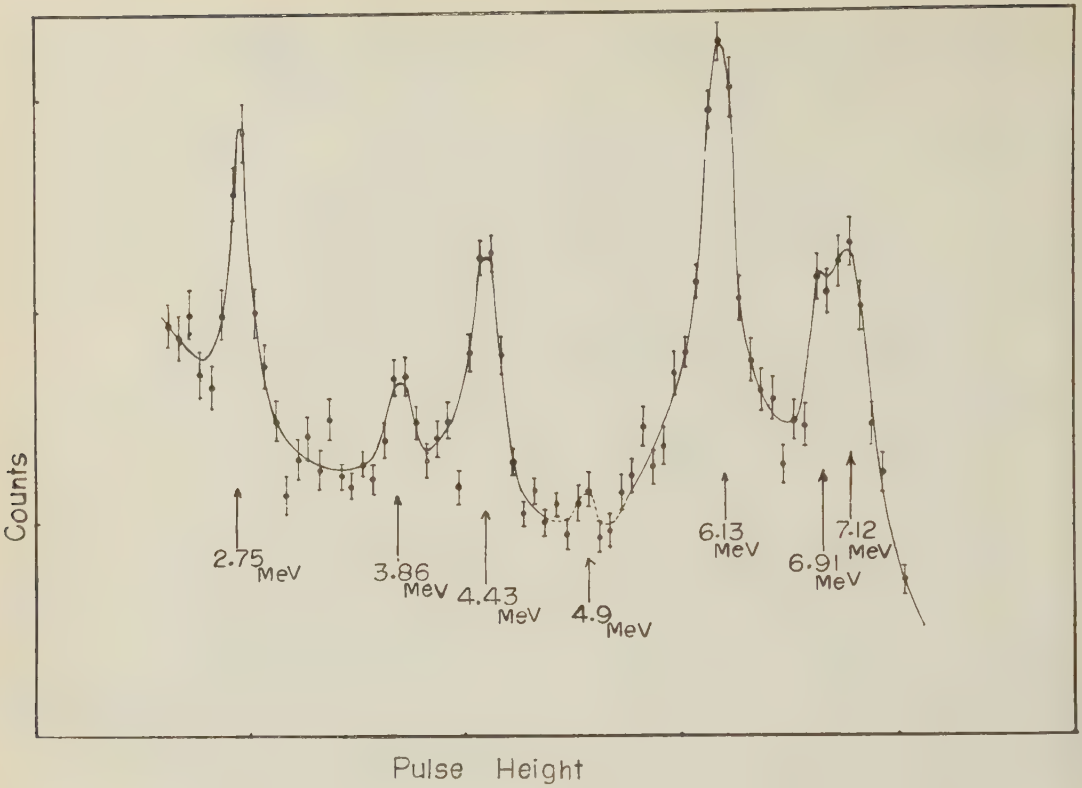

Fig. 2. Three-crystal pair spectrum; Teflon+p at 5.7 MeV and 90° with respect to the proton beam.

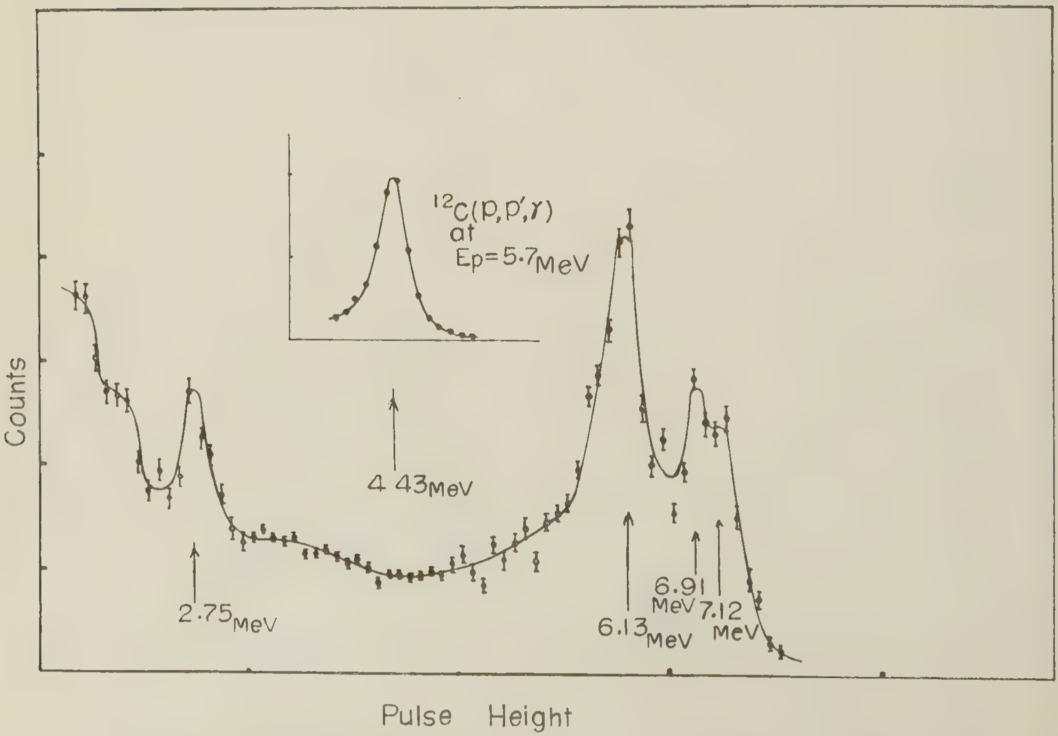

Fig. 3. Three crystal pair spectrum; Teflon+p at 4.8 MeV and 90° with respect to the proton beam.

Fig. 3 shows the gamma ray spectrum when he incident proton energy was lowered to .8 Mev. It is evident from Fig. 3 that new amma rays of 3.86 and 4.9 MeV disappeared t this energy while all the gamma rays of ther energies are still observed.

While the 4.9 MeV gamma ray was too veak to be investigated further, the intensity f 3.68 MeV gamma ray was enough for urther work.

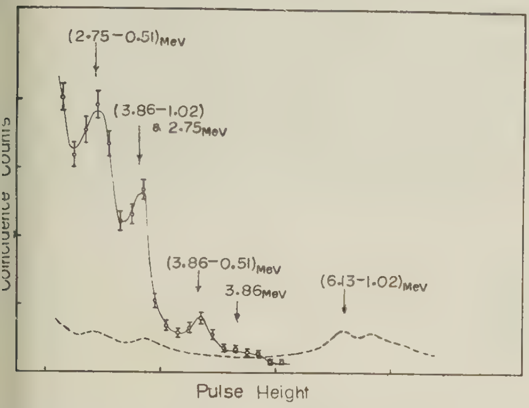

Fig. 4. Gamma ray spectrum in coincidence with gamma rays of energy larger than 4 MeV; BaF_2+p at 5.7 MeV and 90° with respect to the proton beam.

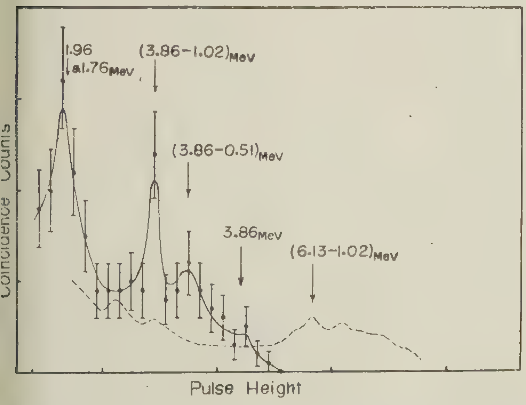

Fig. 5. Gamma ray spectrum in coincidence with gamma rays of energy larger than 6.3 MeV; BaF_2+p at 5.7 MeV and 90° with respect to the proton beam.

The energy measurement was made with he three crystal spectrometer and the value .86±0.02 MeV was obtained after the careful heck of the linearity between pulse heights nd gamma ray energies.

To investigate the origin of 3.86 MeV amma radiation, gamma-gamma coincidence experiments were performed with two NaI (T1) crystals each at 90° to the beam on each side of the target.

Fig. 4 and Fig. 5 are the gamma ray spectra in coincidence with gamma rays whose energies are greater than 4.0 MeV and 6.3 MeV respectively. The dotted line represents the upper limit of background counts calculated from surplus counts in the 20 channel analyser and the pulse height distribution in each single crystal spectrometer.

In identifying the energies to the peaks in Fig. 4 and Fig. 5, the knowledge of the pulse height distribution for monochromatic gamma ray for the same crystal is necessary. The pulse height distribution shown in Fig. 6 was obtained for the 4.43 MeV gamma ray under the same experimental conditions (1½ inch dia., 1½ inch length, NaI(T1)).

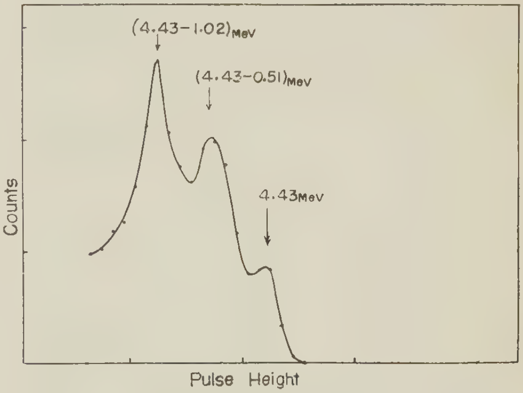

Fig. 6. Singles spectrum of 4.43 MeV gamma radiation.

From these results it is concluded that the 3.86 MeV gamma ray is emitted in cascade with the 7 MeV gamma ray (6.91 or 7.12 MeV) while the 2.75 MeV gamma ray is in cascade with the 6.13 MeV gamma ray. Therefore both of them are the deexcitation gamma rays from the excited states of ^{16}O at about 11 MeV (10.77 or 10.98 MeV) and 8.87 MeV respectively. The latter result with the 2.75 MeV gamma ray is in agreement with the work of Wilkinson et al.

If we assume that the 3.86 MeV gamma radiation originates from the 10.77 MeV state, transition to the 6.13 or 6.06 MeV state from this state will produce a gamma radiation of 4.64 or 4.71 MeV respectively. The gamma radiation corresponding to those energies was not observed and the intensity was estimated to be less than 1/10 of the 3.86 MeV radiation.

If we assume that the 3.86 MeV gamma radiation comes from the 10.98 MeV state, the energy of gamma radiation corresponding to the transition to 6.13 or 6.06 MeV will be 4.85 or 4.92 MeV respectively. The observed 4.9 MeV radiation just coincides with those energy and the intensity is about 1/4 of the 3.86 MeV radiation.

Next, a search for hard gamma radiations due to direct transitions from the 11 and 8.87 MeV states to the ground state was made using both single crystal and three crystal spectrometers.

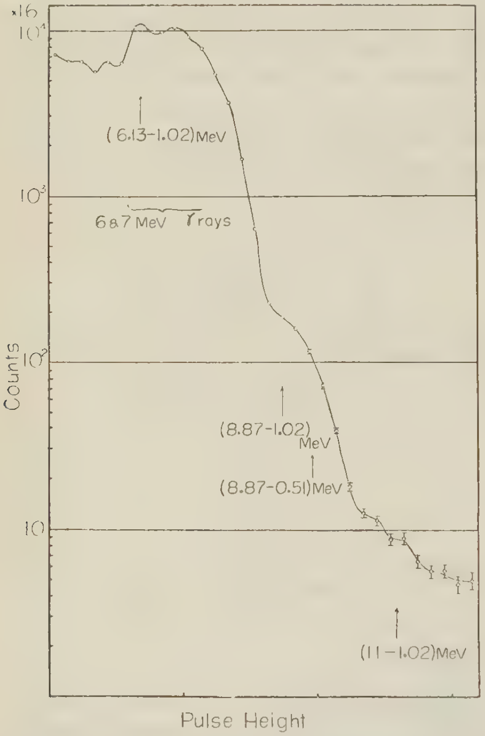

Fig. 7. Singles spectrum in search for hard gamma ray; F+*p* at 5.7 MeV and 90° with respect to the proton beam.

From the single crystal spectrum shown in Fig. 7, it is apparent that the 8.87 and 11 MeV gamma rays are emitted at E_p=5.7 MeV. The intensity of the 8.87 MeV radiation relative to the 2.75 MeV radiation was about 1/160 while that of the 11 MeV radiation relative to the 3.86 MeV radiation was found to be about 10^{-3} correcting for the efficiencies of scintillater for each gamma ray energies. At proton energy of 4.8 MeV (Fig. 8) both gamma rays are observed bu the intensity of the 11 MeV radiation relativ to the 6 and 7 MeV (joint intensity) gamm radiation increased considerably compared t the case of E_p=5.7 MeV.

Fig. 9 shows the excitation curves for th 6 and 7 MeV gamma radiations and the 1 MeV gamma radiation respectively in th proton energy region between 4.8 and 5. MeV.

The intensity of the 11 MeV radiation re lative to the 6 and 7 MeV radiations increase by a factor of 3.7 when the proton energy i lowered from 5.7 MeV to 4.8 MeV. If th 11 MeV radiation is the direct transitio gamma ray to the ground state, the 3.8 MeV peak in pulse height distribution shoul increase by the above ratio at proton energ of 4.8 MeV. As is evident from Fig. 3, th 3.86 MeV peak does not increase but disappears.

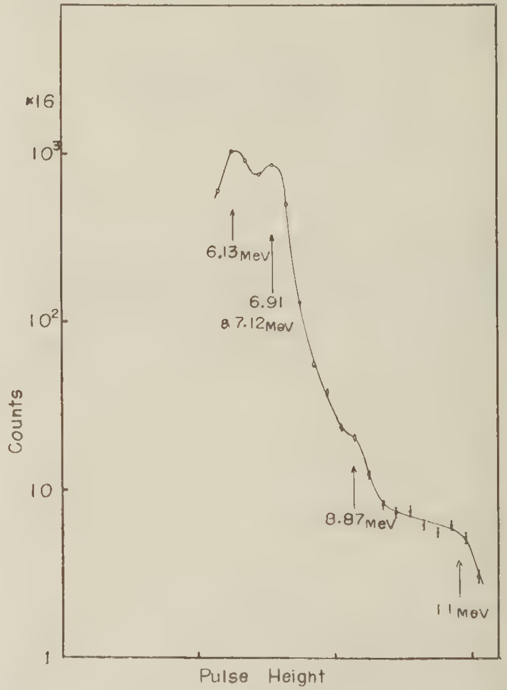

Fig. 8. Three crystal pair spectrum; F+*p* at 4.8 MeV and 90° with respect to the proto beam.

From this fact, it is concluded that th origin of the observed 11 MeV gamma radiation is different from that of the 3.86 Me radiation. Perhaps it is emitted from ^{20}N formed by the capture of proton by ^{19} nucles.

As to the 8.87 MeV radiation, its strength (M2) relative to the 2.75 MeV (M1) radiation would be predicted to be 1/90 by the use of Weisskopf's formula based on the single particle model if 2^- is assigned to the 8.87 MeV state[2]. The value obtained by our observation (1/160) does not conflict with the experimental upper limit 0.15 given by Wilkinson et al.[2], and is in good agreement with theoretical prediction, justifying the 2^- assignment to 8.87 MeV state.

We then tried to estimate the spin and parity of the 11 MeV state from the observed branching ratios of gamma radiations from this state.

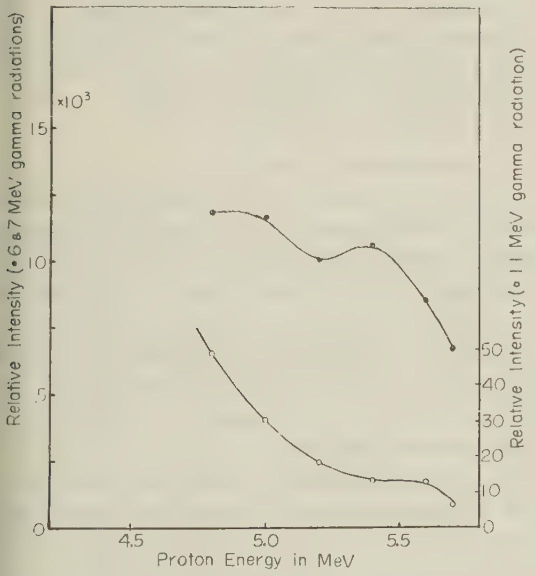

Fig. 9. Excitation curve for 6 and 7 MeV gamma radiations (upper curve) and 11 MeV gamma radiation (lower curve).

Since ^{16}O above an excitation of 7.15 MeV is energetically unstable against break up into ^{12}C in its O^+ ground state and an alpha particle, we have restricted ourselves to the examination of 0^-, 1^+, 2^-, 3^+ only.

We shall discuss exclusively by the use of the single particle formula as the calculation on transition probabilities based on the alpha particle model is not available for indivisual cases.

As the E1 transition is forbidden in ^{16}O by the isotopic spin selection rule and its inhibition factor amounts to a factor of 100 to 1000,[2] an inhibition factor 500 was assumed for E1 radiations.

We shall examine the indivisual case in the following: O^-: Assignment of O^- to the 11 MeV state results in ascribing the 3.86 MeV radiation as a M1 transition from the 10.98 MeV state to the 7.12 MeV (1^-) state. The ground state transition is forbidden, in accordance with experimental result. The intensity of the 4.85 MeV gamma radiation corresponding to the transition from the 10.98 MeV to 6.13 MeV (3^-) state is estimated to be 2×10^{-8} of the 3.86 MeV radiation. Therefore, though the observed gamma radiation of about 4.9 MeV is close to 4.84 MeV in energy, it must find another explanation on intensity consideration.

1^+: In this case the energy of the 11 MeV state must be 10.77 MeV as the transition probability from this state to the 6.91 MeV (2^+) state is estimated to be about 20 times larger than that to the 7.12 MeV (1^-) state. The direct transition to the ground state has larger probability than the transition to the 6.91 MeV state by a factor of 20, contrary to the experiment. Therefore 1^+ assignment is abandoned.

2^-: The transition probability from the 2^- 11 MeV state to the 7.12 MeV state is estimated to be 15 times larger than that to the 6.91 MeV state. The transition from the 10.98 MeV state to the 6.13 MeV (3^-) state is estimated to yield a 4.85 MeV gamma radiation with probability about 1/2 of the 3.86 MeV radiation. In this way the observed 4.9 MeV radiation can be explained. The intensity ratio of 10.98 MeV gamma radiation to 3.86 MeV radiation is calculated to be about 1/180. This is very large compared to the experimental upper limit of about 10^{-4}. Thus 2^- is also abandoned.

3^+: The 3.86 MeV gamma radiation is interpreted as a M1 radiation from the 10.77 MeV (3^+) state to the 6.91 MeV (2^-) state. The intensity of the 10.77 MeV radiation relative to the 3.86 MeV radiation is estimated to be about 10^{-5}, which is consistent with the experiment. The transition from the 10.77 MeV state to the 6.13 MeV (3^-) state will produce a 4.64 MeV radiation about 1/10 of the 3.86 MeV radiation in intensity. This value is not in contradiction with our observation. The transition probabilities from the 10.77 MeV (3^+) state were also calculated on the alpha particle model by R. Nakajima in our laboratory. His results show that the intensity ratio of 10.77 MeV radiation and 3.86 MeV radiation is about 1/70.

After all, the spin and parity for 11 MeV state deduced from the single particle model is either 0^- or 3^+. For the latter assignment, the calculation by the alpha particle model, however, gives too large probability for the transition from the 11 MeV state to the ground state as compared with the experiment.

Next we shall compare the energy for the excited state deduced from this experiment (10.98 MeV (0^-) or 10.77 MeV (3^+)) with the values obtained in other experiments.

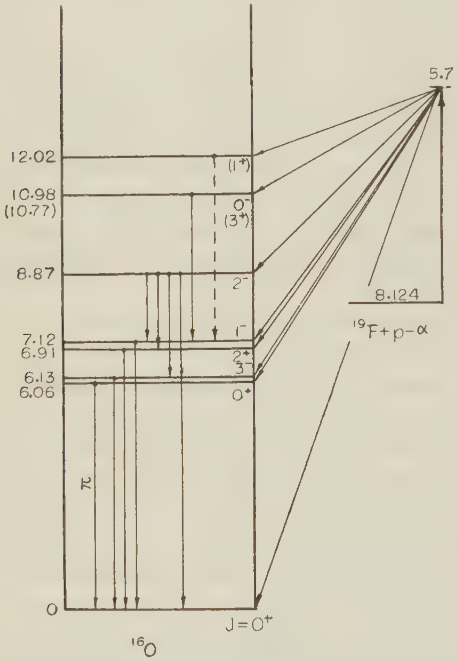

Fig. 10. Energy level diagram of ^{16}O up to 12.08 MeV.

Hornyak and Sherr[4)] observed an excited state of ^{16}O at 11.08 MeV by the analysis of protons inelastically scattered from ^{16}O. They have also confirmed that a gamma radiation is emitted from this state.

Squires, Bockelman and Bruechner[3)] obtained the value 11.085±0.0014 MeV corresponding to this state by precise magnetic analysis of alpha particles emitted in ^{19}F($p\alpha$)^{16}O reaction.

Of the two values 10.98 and 10.77 MeV, the former is more close to the above value, which is in favor of the assignment 0^-.

Recently Bent et al.[7)] in Columbia University report a 3.86 MeV gamma radiatio emitted in ^{19}F($p\alpha$)^{16}O* reaction as in our ex periment. The Columbia group[6)] also foun excited states of ^{16}O at 10.937±0.010 Me and 11.063±0.015 MeV from the study o ^{15}N(d, n)^{16}O reactions. The former value i more close to the value 10.98 MeV obtaine from the gamma ray experiment.

The excited states of ^{16}O relating to th present experiment are shown in Fig. 10.

Considering the above results, it is con cluded that the level at about 11 MeV is pro bably the 10.98 MeV 0^- state.

This conclusion, however, is not very ob jectionable to the alpha particle model, as th assignment 3^+ is in identification (a) i Kamney's article, and in identification (b) th the assignment of 0^- is suggested for th level at about 11.5 MeV.

§ 4. Conclusion

An excited state at 10.98 MeV (or 10.7 MeV) in ^{16}O emits a gamma radiation o 3.86±0.02 MeV energy in transition to th 7.12 MeV (or 6.91 MeV) state. No gamm radiation corresponding to the transition t other lower states was observed. The spi and parity for this state are probably 0^- (o 3^+). Of these two values, 0^- assignmen seems more probable.

A direct transition gamma radiation fro the 8.87 MeV state (2^-) in ^{16}O was observed Its intensity is consistent with single partic considerations.

A capture gamma ray of about 11 Me energy emitted from ^{20}Ne formed by th capture of proton by ^{19}F was observed in th proton energy interval between 4.8 and 5. MeV.

A weak gamma radiation about 4.9 MeV i energy was found and was tentatively as signed to the transition from 12.02 MeV t 7.12 MeV state in ^{16}O.

§ 5. Acknowledgments

The authors wish to thank Prof. S. Kiku chi for his kind interest in this work, an Prof. T. Toyoda, Mr. K. Sugimoto and Mr R. Nakajima for their discussions.

Theory of Excitations in Liquid Helium 4

By Fumihiko TAKANO

Physics Department, Tokyo University of Education, Tokyo

(Received June 1, 1957)

A modified "phonon-roton" model for liquid Helium II is proposed and is shown to be connected smoothly with the theory of Bose condensation. The method used is the direct extension of the method of "auxiliary variables" used by Bogolyubov and Zubarev, and is equivalent to that used by Bohm and Pines in the theory of the electron gas in metals. The phonon excitation is described in terms of the density operator, and the roton part by the so-called individual coordinates. The elimination of the kinematical interaction leads to the following model: The excitations for long wave length are described by phonons, and for short wave length by rotons, and the total number of excitations cannot exceed the total number of the particles. The thermal properties of this model is seen to agree with the experimental fact qualitatively.

§ 1. Introduction

The peculiar properties of liquid He^4 at very low temperatures have been one of the most interesting subjects in low temperature physics since their discovery. The phenomenological theory, usually called two fluid theory, has been very successful to explain these properties. In this theory, the liquid helium is assumed to be composed of two interpenetrating components. One has the properties which are same in all respects as those of the usual liquids and is called the normal fluid part. The other is called the superfluid part and has quite different properties from the normal part.

The derivation of this two-fluid model from the first principle and the explanation of the λ-transition are very interesting subjects for theoretical physicists. The first proposal was due to London$^{1)}$, who noted that the He^4 atoms obeyed Bose statistics and the ideal He^4 gas with the density of the liquid underwent the Bose condensation at the temperature very near to the λ-point of real liquid He^4. Then, Tisza$^{2)}$, proposed the idea that, below this Bose condensation temperature, the particles in the lowest energy level were the superfluid part of the liquid helium and the remainder were the normal fluid part. Although these theories are based upon the ideal gas model, the explanation of λ-transition in terms of Bose condensation is supposed to be true and supported by the fact that the isotope He^3 obeying Fermi statistics does not exhibit any such transition. Recently, Penrose and Onsager[3] showed that "there exists Bose condensation" in liquid He^4 at 0°K by only assuming the absence of the long range order, and at finite temperatures using the Feynman's expression[4] for the partition function.

On the other hand, Landau[5] proposed a quite different point of view. His idea is that the excitations in liquid He^4 are essentially different from those in the ideal gas, and consist of the so-called "phonons" and "rotons" with the following spectrum,

$$\mathcal{E}(k)=\begin{cases}\hbar ck\,, & \text{for phonons,}\\ \Delta+\dfrac{\hbar^2}{2\mu}(k-k_0)^2\,, & \text{for rotons.}\end{cases} \tag{1.1}$$

By choosing appropriate values of the adjusting parameters Δ, μ and k_0, he succeeded to explain various properties of liquid helium. In this theory, the normal fluid density ρ_n is calculated from the inertia of the excitations and the superfluid density ρ_s is equated to $\rho_0-\rho_n$ (ρ_0 is the density of the liquid helium). The λ-point is defined as the temperature at which $\rho_n=\rho_0$, $\rho_s=0$. But nothing can be said about the transition.

Since then, many authors have tried to derive this "phonon-roton" model from the first principle or to revise the Landau's idea by quantizing the classical hydrodynamics in a similar way as in the case of the quantum electrodynamics (quantum hydrodynamics[6]). Although these authors succeeded in some respects, it does not seem that any of them succeeded to explain the presence of the phase transition.

As mentioned above, it is perhaps certain that the transition is due to the Bose statistics. Brenig[7] proposed the model in which the number of rotons was restricted and the Bose condensation could occur. However, his model does not seem to have a concrete basis. It is one of the purposes of this paper to connect the phonon-roton model with the Bose condensation theory more smoothly.

The other purpose of this paper is to write down the interactions among excitations explicitly. This is necessary, for example, for the calculation of the viscosity coefficient This is done by Usui and Matsudaira[8], wh adopted the procedure used by Dyson[9] in hi theory of spin wave interactions in ferromagnets, and took $b_k^+=\frac{1}{\sqrt{N}}c_k^+c_0$ as the creation operator of the excitation with wave numbe k, where c_k, c_k^+ are usual operators whic annihilate and creat the particle with momentum $\hbar k$, respectively. However, their Hamiltonian, although rigorous, contains interactio terms up to sixth power of b_k or b_k^+, and s is very inconvenient to deal with. This show that their choice of b_k^+ was inadequate.

Many authors took the density operator

$$\rho_k=\frac{1}{\sqrt{N}}\sum_{j=1}^{N}e^{ikx_j}=\frac{1}{\sqrt{N}}\sum_{K}c_{K+k}^{+}c_K \qquad (1\,2$$

as the variables describing phonons. For rotons, however, it is not clear what coordinat is to be taken. For Bose systems, it is no impossible to describe all the excitations i terms of ρ_k's only. But it seems that ρ_k' are variables not so appropriate to short wav length excitations (rotons) as they are to lon wave length excitations (phonons). We consider the roton excitations as particle-like Then the problem reduces to one of the collective descriptions in which the collectiv coordinate corresponds to phonons and th individual one to rotons. Nishiyama[10] an Brenig[7] attempted to derive the phonon-roto spectrum (1.1) using the method of Tomonaga[11]. However, since the Hamiltonian cannot be written in a closed form by the metho of Tomonaga, we resort to a different method which is a direct extension of the method o the "auxiliary variables" used by Bogolyubo and Zubarev[12]. The Hamiltonian obtained i equivalent to the one which Bohm and Pines[13] used in the case of the electron gas in metals

The elimination of what Dyson calls th "kinematical interaction" leads to the following model: The excitations are composed o two parts. For long wave length the excitations are described by ρ_k's (phonons) and fo short wave length the excitations are particle-like (rotons). Moreover, the total number o the excitations cannot exceed the total numbe of particles, leading to the Bose condensatio of second order. Thus the two purposes mentioned above can be achieved.

§ 2. Hamiltonian

As was mentioned in § 1, we take $\rho_{\boldsymbol{k}}$'s, Eq. (1.2), as the variables describing the phonon excitations and the individual coordinates $\boldsymbol{x}_j$'s as the roton excitations. The Hamiltonian which describes the motions of these $\rho_{\boldsymbol{k}}$'s as well as $\boldsymbol{x}_j$'s is constructed in the following way. The method is an extension of that used by Bogolyubov and Zubarev[12], and is applicable for the variables other than $\rho_{\boldsymbol{k}}$'s, but here, for simplicity, we treat only the case of $\rho_{\boldsymbol{k}}$'s. As was mentioned in § 1, $\rho_{\boldsymbol{k}}$'s are good variables for small k, but for large k they are no longer supposed to be good. So we restrict $\rho_{\boldsymbol{k}}$'s only for $|\boldsymbol{k}| \leq k_c$, k_c being determined later.

The Hamiltonian for the system of N identical particles with the mass m is written as

$$H = -\frac{\hbar^2}{2m}\sum_{j=1}^{N}\Delta_j + \frac{1}{2}\sum_{i \neq j}\sum G(r_{ij}) = T + G\ , \tag{2.1}$$

where Δ_j is the Laplacian operator for the j-h particle, and $G(r)$ is the interaction energy between two particles with mutual distance r. f we expand $G(r)$ in Fourier series*

$$G(r) = \frac{1}{V}\sum_{\boldsymbol{k}} G(k) e^{i\boldsymbol{k}\boldsymbol{r}}\ , \quad G(k) = \int G(r)\, e^{-i\boldsymbol{k}\boldsymbol{r}} d\boldsymbol{r}\ , \tag{2.2}$$

then the interaction part G of Eq. (2.1) becomes

$$\begin{aligned} G = {} & \frac{N}{2V}\sum_{0<|\boldsymbol{k}|\leq k_c} G(k)\rho_{\boldsymbol{k}}\rho_{-\boldsymbol{k}} - \frac{N}{2V}\sum_{0<|\boldsymbol{k}|\leq k_c} G(k) \\ & + \frac{1}{2V}\sum_{i \neq j}\sum_{k_c<|\boldsymbol{k}|} G(k)\, e^{i\boldsymbol{k}(\boldsymbol{x}_i-\boldsymbol{x}_j)} + \frac{N^2}{2V} G(0)\ . \end{aligned} \tag{2.3}$$

The kinetic energy T of Eq. (2.1) is written down as follows. We consider that the wave unction Ψ includes $\rho_{\boldsymbol{k}}$'s as well as the particle coordinates $\boldsymbol{x}_j$'s. Then the differential operator in T is written as

$$\begin{aligned} \frac{\partial\Psi}{\partial\boldsymbol{x}_j} & = \left(\frac{\partial\Psi}{\partial\boldsymbol{x}_j}\right)_\rho + \sum_{0<|\boldsymbol{k}|\leq k_c}\frac{\partial\rho_{\boldsymbol{k}}}{\partial\boldsymbol{x}_j}\left(\frac{\partial\Psi}{\partial\rho_{\boldsymbol{k}}}\right)_x \\ & = \left(\frac{\partial\Psi}{\partial\boldsymbol{x}_j}\right)_\rho + \frac{1}{\sqrt{N}}\sum_{0<|\boldsymbol{k}|\leq k_c} i\boldsymbol{k}\, e^{i\boldsymbol{k}\boldsymbol{x}_j}\left(\frac{\partial\Psi}{\partial\rho_{\boldsymbol{k}}}\right)_x \end{aligned} \tag{2.4}$$

$$\begin{aligned} \frac{\partial^2\Psi}{\partial\boldsymbol{x}_j^2} = {} & \left(\frac{\partial^2\Psi}{\partial\boldsymbol{x}_j^2}\right)_\rho + \frac{2}{\sqrt{N}}\sum_{0<|\boldsymbol{k}|\leq k_c} i\boldsymbol{k}\, e^{i\boldsymbol{k}\boldsymbol{x}_j}\frac{\partial^2\Psi}{\partial\boldsymbol{x}_j\partial\rho_{\boldsymbol{k}}} \\ & - \frac{1}{\sqrt{N}}\sum_{0<|\boldsymbol{k}|\leq k_c}\boldsymbol{k}^2\, e^{i\boldsymbol{k}\boldsymbol{x}_j}\frac{\partial\Psi}{\partial\rho_{\boldsymbol{k}}} \\ & - \frac{1}{\sqrt{N}}\sum_{0<|\boldsymbol{k}|,\,|\boldsymbol{k}|\leq k_c}\sum (\boldsymbol{k}\cdot\boldsymbol{k}')\, e^{i(\boldsymbol{k}+\boldsymbol{k})\boldsymbol{x}_j}\frac{\partial^2\Psi}{\partial\rho_{\boldsymbol{k}}\partial\rho_{\boldsymbol{k}'}}\ . \end{aligned} \tag{2.5}$$

Summing both sides of Eq. (2.5) over j, and considering $\rho_{\boldsymbol{k}}$'s as independent variables, the kinetic energy T can be written as

$$\begin{aligned} T = {} & \frac{1}{2m}\sum_{j=1}^{N}\boldsymbol{p}_j^2 \\ & + \frac{1}{\sqrt{N}}\sum_{j=1}^{N}\sum_{0<|\boldsymbol{k}|\leq k_c} e^{i\boldsymbol{k}\boldsymbol{x}_j}\frac{\hbar\boldsymbol{k}}{2m}\cdot\boldsymbol{p}_j\frac{\partial}{\partial\rho_{\boldsymbol{k}}} \\ & + \sum_{0<|\boldsymbol{k}|\leq k_c}\frac{\hbar^2 k^2}{2m}\rho_{\boldsymbol{k}}\frac{\partial}{\partial\rho_{\boldsymbol{k}}} \\ & + \frac{1}{\sqrt{N}}\sum_{\substack{0<|\boldsymbol{k}|,\,|\boldsymbol{k}'|\leq k_c \\ 0<|\boldsymbol{k}+\boldsymbol{k}'|\leq k_c}}\sum\frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m}\rho_{\boldsymbol{k}+\boldsymbol{k}'}\frac{\partial^2}{\partial\rho_{\boldsymbol{k}}\partial\rho_{\boldsymbol{k}'}} \\ & - \sum_{0<|\boldsymbol{k}|\leq k_c}\frac{\hbar^2 k^2}{2m}\frac{\partial^2}{\partial\rho_{\boldsymbol{k}}\partial\rho_{-\boldsymbol{k}}} \\ & + \frac{1}{N}\sum_{j=1}^{N}\sum_{\substack{0<|\boldsymbol{k}|,\,|\boldsymbol{k}'|\leq k_c \\ k_c<|\boldsymbol{k}+\boldsymbol{k}'|}}\sum\frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m}e^{i(\boldsymbol{k}+\boldsymbol{k}')\boldsymbol{x}_j}\frac{\partial^2}{\partial\rho_{\boldsymbol{k}}\partial\rho_{\boldsymbol{k}'}}\ . \end{aligned} \tag{2.6}$$

Thus, the total Hamiltonian can be written as

$$\mathscr{H} = \mathscr{H}_{\text{col.}} + \mathscr{H}_{\text{ind.}} + \mathscr{H}_{\text{int.}}\ , \tag{2.7}$$

where the collective part $\mathscr{H}_{\text{col.}}$ is

$$\begin{aligned} \mathscr{H}_{\text{col.}} = {} & \sum_{0<|\boldsymbol{k}|\leq k_c}\left\{-\frac{\hbar^2 k^2}{2m}\frac{\partial^2}{\partial\rho_{\boldsymbol{k}}\partial\rho_{-\boldsymbol{k}}} + \frac{N}{2V}G(k)\rho_{\boldsymbol{k}}\rho_{-\boldsymbol{k}}\right\} \\ & + \frac{1}{\sqrt{N}}\sum_{\substack{0<|\boldsymbol{k}|,\,|\boldsymbol{k}'|\leq k_c \\ 0<|\boldsymbol{k}+\boldsymbol{k}'|\leq k_c}}\sum\frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m}\rho_{\boldsymbol{k}+\boldsymbol{k}'}\frac{\partial^2}{\partial\rho_{\boldsymbol{k}}\partial\rho_{\boldsymbol{k}'}} \\ & - \frac{N}{2V}\sum_{0<|\boldsymbol{k}|\leq k_c} G(k) + \frac{N^2}{2V}G(0)\ , \end{aligned} \tag{2.7a}$$

and the individual part $\mathscr{H}_{\text{ind.}}$ is

$$\begin{aligned} \mathscr{H}_{\text{ind.}} = {} & \frac{1}{2m}\sum_{j=1}^{N}\boldsymbol{p}_j^2 \\ & + \frac{1}{2V}\sum_{i \neq j}\sum\sum_{k_c<|\boldsymbol{k}|} G(k)\, e^{i\boldsymbol{k}(\boldsymbol{x}_i-\boldsymbol{x}_j)}\ , \end{aligned} \tag{2.7b}$$

and the interaction part $\mathscr{H}_{\text{int.}}$ is

$$\begin{aligned} \mathscr{H}_{\text{int.}} = {} & \frac{1}{\sqrt{N}}\sum_{j=1}^{N}\sum_{0<|\boldsymbol{k}|\leq k_c}\frac{\hbar\boldsymbol{k}}{2m}(e^{i\boldsymbol{k}\boldsymbol{x}_j}\boldsymbol{p}_j + \boldsymbol{p}_j e^{i\boldsymbol{k}\boldsymbol{x}_j})\frac{\partial}{\partial\rho_{\boldsymbol{k}}} \\ & + \frac{1}{N}\sum_{j=1}^{N}\sum_{\substack{0<|\boldsymbol{k}|,\,|\boldsymbol{k}'|\leq k_c \\ k_c<|\boldsymbol{k}+\boldsymbol{k}'|}}\sum\frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m}e^{i(\boldsymbol{k}+\boldsymbol{k}')\boldsymbol{x}_j}\frac{\partial^2}{\partial\rho_{\boldsymbol{k}}\partial\rho_{\boldsymbol{k}'}}\ . \end{aligned} \tag{2.7c}$$

---

* Actually, this Fourier expansion is not pos-ible due to the presence of the strong repulsive nteraction of short range between Helium atoms. Here, we neglect this fact temporarily, and shall iscuss this problem in § 6.

If we set $\boldsymbol{p}_j=0$ for all j, that is, if the wave function does not contain $\boldsymbol{x}_j$'s explicitly (this is allowed only for Bose systems), and put $k_c\to\infty$, then the Hamiltonian $\mathscr{H}$ is reduced to that used by Bogolyubov and Zubarev[12], who attempted to describe the motion of the system only in terms of the density $\rho_{\boldsymbol{k}}$. In this case, $\mathscr{H}_{\text{ind.}}=0$, and the second term in $\mathscr{H}_{\text{int.}}$ vanishes and the first term reduces to the form $\sum_{\boldsymbol{k}}\dfrac{\hbar^2k^2}{2m}\rho_k\dfrac{\partial}{\partial\rho_k}$, which makes the Hamiltonian of Bogolyubov and Zubarev non-Hermitian*. Here, we adopt the form of Eq. (2.7c) in order to keep the Hermitian property of our Hamiltonian.

Moreover, the Hamiltonian (2.7) is equivalent to that used by Bohm and Pines[13], as is easily seen when we set

$$\rho_k=\frac{-ik}{\sqrt{4\pi Ne}}p_k\,,\qquad \frac{\partial}{\partial\rho_k}=\frac{\sqrt{4\pi N}}{\hbar k}eq_k\,.$$

That is to say, the method of Bogolyubov and Zubarev is a special case of Bohm and Pines.

The second term of Eq. (2.7a) is considered to be small by Bohm and Pines[13] by the random phase approximation, and is completely neglected by Brenig[7], who assumes the orthogonality of $\rho_{\boldsymbol{k}}$'s. But since the number of the modes considered is very large, this term cannot completely be neglected. For, even if the error resulting from this assumption is of the order of $1/\sqrt{N}$ for each mode, the total error for all modes is very large. In fact, this term represents the interactions among phonons, and is necessary for the calculation of the viscosity coefficient.

The Hamiltonian $\mathscr{H}$, Eq. (2.7), contains excess number of independent variables. Usually, this is avoided by setting the subsidiary conditions

$$\rho_k-\frac{1}{\sqrt{N}}\sum_{j=1}^{N}e^{i\boldsymbol{k}\boldsymbol{x}_j}=0\,,\qquad 0<|\boldsymbol{k}|\leqslant k_c\,. \tag{2.8}$$

However, this method is too formal and inconvenient to deal with. It is very difficul to find the wave functions satisfying thes conditions (2.8), and, in fact, such wave func tions have never been found in literatures The problem how to avoid this excess of th independent variables corresponds to wha Dyson[9] calls the "kinematical interactions. To eliminate this kinematical interactions w do not use the subsidiary conditions (2.8), bu use a quite different method, which will b discussed in § 4.

§ 3. Energy Spectrum

To obtain the energy spectrum of the ex citation, we must diagonalize the Hamiltonian First, we consider the collective part $\mathscr{H}_{\text{col.}}$ (2.7a), which is separated into two parts,

$$\mathscr{H}_{\text{col.}}=\mathscr{H}_{\text{phon.}}+\mathscr{H}'\,, \qquad (3.$$

where

$$\begin{aligned}\mathscr{H}_{\text{phon.}}=\sum_{0<|\boldsymbol{k}|\leq k_c}&\left\{-\frac{\hbar^2k^2}{2m}\frac{\partial^2}{\partial\rho_k\partial\rho_{-k}}\right.\\&\left.+\frac{N}{2V}G(k)\rho_k\rho_{-k}\right\}\\&-\frac{N}{2V}\sum_{0<|\boldsymbol{k}|\leq k_c}G(k)+\frac{N^2}{2V}G(0)\end{aligned} \qquad (3.1$$

is the phonon energy, and

$$\mathscr{H}'=\frac{1}{\sqrt{N}}\sum_{\substack{0<|\boldsymbol{k}|,|\boldsymbol{k}'|\leq k_c\\0<|\boldsymbol{k}+\boldsymbol{k}'|<k_c}}\sum\frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m}\rho_{\boldsymbol{k}+\boldsymbol{k}'}\frac{\partial^2}{\partial\rho_k\partial\rho_{k'}} \qquad (3.1$$

is the interaction energy among phonons, was mentioned above. Now, we introduce th annihibilation and creation operator b_k, b_k^+ phonons as follows

$$\left.\begin{aligned}\rho_k&=\sqrt{\frac{T(k)}{E(k)}}(b_k^{\,+}+b_{-k})\,,\\\frac{\partial}{\partial\rho_k}&=\frac{1}{2}\sqrt{\frac{E(k)}{T(k)}}(b_k-b^+_{-k})\,,\end{aligned}\right\} \qquad (3.$$

where b_k, b_k^+ satisfy the commutation relati

$$[b_k,b^+_{k'}]=\delta_{k,k'}\,, \qquad (3.$$

and

$$\left.\begin{aligned}T(k)&=\frac{\hbar^2k^2}{2m}\,,\\E(k)&=2\left[T(k)\frac{N}{2V}G(k)\right]^{1/2}.\end{aligned}\right\} \qquad (3.$$

Then, $\mathscr{H}_{\text{phon.}}$, (3.1a) becomes immediately

---

* When we set $\boldsymbol{p}_j=0$ and the number of ρ_k's is equal to $3N$, our transformation of the Hamiltonian can be considered as the transformation of variables from $\boldsymbol{x}_j$'s to ρ_k's. Then, if we take into consideration the Jacobian of this transformation, the transformed Hamiltonian must remain Hermitian. But since ρ_k's are treated as independent variables, the Hamiltonian of Bogolyubov and Zubarev seems to be non-Hermitian.

$$\mathscr{H}_{\text{phon.}} = \sum_{0<|\boldsymbol{k}|\leq k_c} \left\{ \frac{1}{2} E(k)(b_{\boldsymbol{k}}^{+}b_{\boldsymbol{k}} + b_{\boldsymbol{k}}b_{\boldsymbol{k}}^{+}) - \frac{N}{2V} G(k) \right\} + \frac{N^2}{2V} G(0) . \tag{3.5}$$

Thus, the phonon energy is given by $E(k)$, Eq. (3.4). For small values of k, $E(k)$ is proportional to k,

$$E(k) \simeq \hbar \sqrt{\frac{NG(0)}{mV}}\, k , \qquad \text{for small } k, \tag{3.6}$$

as can be expected. For finite k, strictly speaking, $E(k)$ deviates from linearity to k and show the dispersion.

Using the transformation (3.2), the interaction term $\mathscr{H}'$ can be written as

$$\mathscr{H}' = \frac{1}{\sqrt{N}} \sum_{\substack{0<|\boldsymbol{k}|,|\boldsymbol{k}'|\leq k_c \\ 0<|\boldsymbol{k}+\boldsymbol{k}'|\leq k_c}} \sum \frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m} \frac{\lambda_{|\boldsymbol{k}+\boldsymbol{k}'|}}{\lambda_k \lambda_{k'}} \times \{ b_{\boldsymbol{k}+\boldsymbol{k}'}^{+} b_{-\boldsymbol{k}}^{+} b_{-\boldsymbol{k}'}^{+} + b_{\boldsymbol{k}+\boldsymbol{k}'}^{+} b_{\boldsymbol{k}} b_{\boldsymbol{k}'} - 2 b_{\boldsymbol{k}+\boldsymbol{k}'}^{+} b_{-\boldsymbol{k}}^{+} b_{\boldsymbol{k}'} + \text{c.c.} \} , \tag{3.7}$$

where

$$\lambda_k = [T(k)/E(k)]^{1/2} ,$$

and c.c. represents the operators conjugate to the preceding ones.

On the other hand, $\mathscr{H}_{\text{ind.}}$ has the form

(kinetic energy)+(short range interactions).

As was suggested by Feynman⁴⁾, the excited states of such a system have a wave function of the form

(the permanent of the plane waves)
×(the ground state wave function),

and the excitation energy can be given approximately as

$$\mathcal{E}(k) = \frac{\hbar^2 k^2}{2m^*} , \tag{3.8}$$

where m^* is the effective mass.

Substitution Eq. (3.2) into Eq. (2.7c), leads to

$$\mathscr{H}_{\text{int.}} = \frac{1}{\sqrt{N}} \sum_{j=1}^{N} \sum_{0<|\boldsymbol{k}|\leq k_c} \frac{\hbar \boldsymbol{k}}{2m} \cdot (e^{i\boldsymbol{k}\boldsymbol{x}_j} \boldsymbol{p}_j + \boldsymbol{p}_j e^{i\boldsymbol{k}\boldsymbol{x}_j}) \frac{1}{2\lambda_{\boldsymbol{k}}} (b_{\boldsymbol{k}} - b_{-\boldsymbol{k}}^{+}) + \frac{1}{N} \sum_{j=1}^{N} \sum_{\substack{0<|\boldsymbol{k}|,|\boldsymbol{k}'|\leq k_c \\ k_c<|\boldsymbol{k}+\boldsymbol{k}'|}} \sum \frac{\hbar^2(\boldsymbol{k}\cdot\boldsymbol{k}')}{2m} e^{i(\boldsymbol{k}+\boldsymbol{k}')\boldsymbol{x}_j} \frac{1}{4\lambda_k \lambda_{k'}} \times (b_{-\boldsymbol{k}}^{+} b_{-\boldsymbol{k}'}^{+} - 2 b_{-\boldsymbol{k}}^{+} b_{\boldsymbol{k}'} + b_{\boldsymbol{k}} b_{\boldsymbol{k}'}) . \tag{3.9}$$

Thus, the interactions among various excitations can be written down explicitly. Eq. (3.7) represents the interaction between phonons, and Eq. (3.9) between phonons and rotons. The interactions between rotons are included in $\mathscr{H}_{\text{ind.}}$.

§ 4. Kinematical Interactions

As was mentioned in § 2, our Hamiltonian $\mathscr{H}$ involves excess degrees of freedom. Usually, this excess freedom is avoided by the subsidiary conditions (2.8), which is too formal and inconvenient. Here we use another procedure which is generally applicable to Bose systems.

The basic idea is the following: We consider the Hilbert space which consists of the wave functions which contain $\boldsymbol{x}_j$'s and ρ_k's as independent variables and call this space U. An element of this U-space will be denoted as $|\alpha)$. The Hamiltonian $\mathscr{H}$, Eq. (2.7), is an operator in this U-space. On the other hand, let the Hilbert space which consists of the wave functions which contain $\boldsymbol{x}_j$'s only as independent variables be V, an element of which will be written as $|\alpha\rangle$. The original Hamiltonian H, Eq. (2.1), is an operator in this V-space.

Then we can define an operator P which operates on $|\alpha)$ in U-space and puts it into a state $|\alpha\rangle$ in V-space

$$P|\alpha) = |\alpha\rangle . \tag{4.1}$$

To write down this operation explicitly, we may proceed as follows,

$$P\varphi(\boldsymbol{x}_j;\ \rho_k) = \varphi(\boldsymbol{x}_j;\ \rho_k(\boldsymbol{x}_j)) . \tag{4.2}$$

The meaning of this equation is as follows: When we operate P on any function φ which contains ρ_k's as independent variables, then ρ_k's in $P\varphi$ are no longer regarded as independent variables, and so $P\varphi$ depends on $\boldsymbol{x}_j$'s through ρ_k's as well as explicitly.

Now we take the sub-space U_1 of U-space which has the following property: From complete orthonormal set of functions $|\alpha_1)$, $|\alpha_2)$, $\cdots$ in this sub-space U_1 we can get the set of the functions in V-space, $P|\alpha_1) \equiv |\alpha_1\rangle$, $P|\alpha_2) \equiv |\alpha_2\rangle \cdots$. If we choose U_1 properly, then $|\alpha_1\rangle, |\alpha_2\rangle, \cdots$ can be made linearly independent of each other and, moreover, form a complete set in V-space. That is, any function $|\,\rangle$ in V-space can be expanced in terms of these $|\alpha_j\rangle$'s,

$$|\,\rangle = \sum_j |\alpha_j\rangle c_j \tag{4.3}$$

the coefficients c_j's being determined uniquely.

These $|\alpha_j\rangle$'s are not always normalized and orthogonal to each other, since $\langle\alpha_i|\alpha_j\rangle=(\alpha_i|P|\alpha_j)$ is not always equal to δ_{ij}.

Now let us consider the eigenvalue problem and also the calculation of the trace in V-space in terms of this non-orthogonal set. The result is very simple as shown in the following: For any operator A in V-space, we can write

$$A|\alpha_i\rangle=\sum_j|\alpha_j\rangle A_{ji}\,. \tag{4.4}$$

This is possible because of the completeness of the set $|\alpha_j\rangle$. We can not, however, set $A_{ji}=\langle\alpha_i|A|\alpha_i\rangle$, because $|\alpha_i\rangle$'s are not orthonormal.

Using the coefficients A_{ji}'s in Eq. (4.4), we can write down the secular equation determining eigenvalue a of A as follows,

$$|A_{ji}-a\delta_{ji}|=0\,, \tag{4.5}$$

and the trace of A can be calculated

$$\mathrm{Tr}\,A=\sum_i A_{ii}\,. \tag{4.6}$$

Eqs. (4.5) and (4.6) are obvious because A_{ji} can be considered as a matrix representation of the operator A.

Next let us define the operator $\mathfrak{A}$ in U-space corresponding to the physical observable A in V-space in the following way

$$P\mathfrak{A}=AP\,. \tag{4.7}$$

This procedure is equivalent to that used by Dyson[9)] to construct the operator in the "ideal" space from that in the original space.

That our Hamiltonian $\mathscr{H}$, Eq. (2.7), satisfies the relation (4.7) is seen as follows: The operator A is a function of the particle coordinates $\boldsymbol{x}_j$'s and momenta $\boldsymbol{p}_j$'s. From the relation (4.7) we get

$$P\mathfrak{A}\mathfrak{B}=ABP\,,$$

meaning that if $\mathfrak{A}$ corresponds to A, and $\mathfrak{B}$ to B, then the operator corresponding to AB is $\mathfrak{A}\mathfrak{B}$. Thus it is sufficient to construct the operator in U-space which corresponds to the operators $\boldsymbol{x}_j$'s and $\boldsymbol{p}_j$'s in V-space.

Now we can write for $\boldsymbol{x}_j$:

$$\boldsymbol{x}_jP\varphi(\boldsymbol{x}_j;\ \rho_k)=\boldsymbol{x}_j\varphi(\boldsymbol{x}_j;\ \rho_k(\boldsymbol{x}_j))=P\{\boldsymbol{x}_j\varphi(\boldsymbol{x}_j;\ \rho_k)\}\,.$$

Thus, $\boldsymbol{x}_j$'s need not be rewritten. But when the form $\sum_{j=1}^{N}e^{i\boldsymbol{k}\boldsymbol{x}_j}$ appears, we may write it either as ρ_k or as $\sum_{j=1}^{N}e^{i\boldsymbol{k}\boldsymbol{x}_j}$. Therefore, the arbitrariness of this sort remains in the definition (4.7), showing that Eq. (4.7) is necessary but not sufficient to define $\mathfrak{A}$. We take the form (2.3) for the interaction energy G.

Next, for $\boldsymbol{p}_j$'s we can write

$$\begin{aligned}\frac{\partial}{\partial\boldsymbol{x}_j}P\varphi(\boldsymbol{x}_j;\ \rho_k)&=\frac{\partial}{\partial\boldsymbol{x}_j}\varphi(\boldsymbol{x}_j;\ \rho_k(\boldsymbol{x}_j))\\&=P\left\{\left(\frac{\partial\varphi}{\partial\boldsymbol{x}_j}\right)_\rho+\sum_k\frac{\partial\rho_k}{\partial\boldsymbol{x}_j}\left(\frac{\partial\varphi}{\partial\rho_k}\right)_k\right\}.\end{aligned}$$

This is just the transformation used in Eq. (2.4). Thus, it is proved that our Hamitonian (2.7) satisfies the relation (4.7).

Now, Eq. (4.4) is written in terms of the operator $\mathfrak{A}$ defined by Eq. (4.7),

$$P\mathfrak{A}|\alpha_i)=P\sum_j|\alpha_j)A_{ji}\,. \tag{4.8}$$

In general, $\mathfrak{A}|\alpha_i)$ has components $|\beta_k)$'s orthogonal to U_1,

$$\mathfrak{A}|\alpha_i)=\sum_j|\alpha_j)A_{ji}+\sum_k|\beta_k)A'_{ki}\,. \tag{4.9}$$

From the orthonormal property of $|\alpha_j)$'s in U-space, we can calculate the matrix element A_{ji} in a usually way

$$A_{ji}=(\alpha_j|\mathfrak{A}|\alpha_i)\,. \tag{4.10}$$

Thus the secular equation (4.5) and the trace (4.6) in V-space can be written as

$$|\,(\alpha_j|\mathfrak{A}|\alpha_i)-a\delta_{ji}\,|=0\,, \tag{4.11}$$

and

$$\mathrm{Tr}\,A=\sum_i(\alpha_i|\mathfrak{A}|\alpha_i)\,. \tag{4.12}$$

It is to be noted that in Eqs. (4.11) and (4.12) $|\alpha_j)$'s should not be taken as the complete set of the entire U-space, and A'_{ki} in Eq. (4.9) has no physical meaning. Thus, for example, we must not take $|\beta_k)$'s into consideration even in the intermediate virtual states in the perturbation calculation. It is necessary and sufficient to consider the sub-space U_1 only.

In our case the above-mentioned sub-space U_1 can be constructed easily. According to the arguments in § 3 the wave function of the excited state, in which the phonons with wave numbers $\boldsymbol{k}_1,\cdots,\boldsymbol{k}_m$ and the rotons with wave numbers $\boldsymbol{K}_1,\cdots,\boldsymbol{K}_n$ are excited, has the form in our approximation

$$\begin{aligned}\Phi_i&\equiv\Phi_{\{\boldsymbol{k}_1\cdots\boldsymbol{k}_m;\boldsymbol{K}_1\cdots\boldsymbol{K}_n\}}\\&=\rho_{\boldsymbol{k}_1}\cdots\rho_{\boldsymbol{k}_m}\Psi_{\{\boldsymbol{K}_1\cdots\boldsymbol{K}_m\}}\Phi_0\,,\end{aligned} \tag{4.13}$$

where Φ_0 is the ground state wave function, and $\Psi_{\{\boldsymbol{K}_1\cdots\boldsymbol{K}_n\}}$ is a permanent of plane waves,

$$\Psi_{\{\boldsymbol{K}_1\cdots\boldsymbol{K}_n\}}=\sum_P P\exp\left[i(\boldsymbol{K}_1\boldsymbol{x}_1+\cdots+\boldsymbol{K}_n\boldsymbol{x}_n)\right]\,,$$

where the summation is over all permutations

P of N particles. On the other hand, the functions

$$\begin{aligned}\Psi_i&=\Psi_{\{\boldsymbol{k}_1\cdots\boldsymbol{k}_m,\boldsymbol{K}_1\cdots\boldsymbol{K}_n\}}\\&=\sum_P P\exp[i(\boldsymbol{k}_1\boldsymbol{x}_1+\cdots+\boldsymbol{k}_m\boldsymbol{x}_m+\boldsymbol{K}_1\boldsymbol{x}_{m+1}\\&\qquad+\cdots+\boldsymbol{K}_n\boldsymbol{x}_{n+m})]\,,\quad m+n\leq N\,,\qquad(4.14)\end{aligned}$$

form a complete orthogonal set in V-space. Thus, if we impose the restrictions $|\boldsymbol{k}_i|\leq k_c$, $|\boldsymbol{K}_i|>k_c$ and $m+n\leq N$ on the wave functions (4.13), we can make one-to-one correspondence between the set Φ_i and Ψ_i. Therefore, when such restrictions are imposed on the wave functions (4.13), they form a sub-space U_1 which has the same property as those mentioned above.

In other words, we can say that the roton excitations with wave numbers smaller than k_c are inhibited and the excitations for $|\boldsymbol{k}|\leq k_c$ are described only in terms of phonons, and that the total number of these excitations cannot exceed the total number N of the particles*.

The above argument applies only to Bose systems. In Fermi systems, it is not possible to describe the excitations only in terms of ρ_k's even for small $|\boldsymbol{k}|$. This is possibly the reason why liquid He^3 obeying Fermi statistics exhibits quite different behaviors from those of liquid He^4.

In the case of the electron gas in metals, treated by Bohm and Pines[13)], the collective oscillations, usually called plasma oscillations, have very high frequencies compared with the individual excitation energies. Hence if the temperature is not so high, the plasma excitations may be neglected, and we need consider only the individual oscillations. In this case, the sub-space U_1 consists of the individual excitations only. Thus, the usual procedure in which we neglect the presence of the subsidiary conditions is justified. However, in the case when the plasma excitations play an important role, it is necessary to consider this problem more carefully.

§ 5. The Bose Condensation

From the arguments in § 3 and § 4, we can derive the following model for the liquid helium 4: The total energy can be written as

$$E=E_0+\sum_{\boldsymbol{k}} n(\boldsymbol{k})\mathcal{E}(\boldsymbol{k})\,,\qquad(5.1)$$

where E_0 is the ground state energy, and $\mathcal{E}(\boldsymbol{k})$ is given by

$$\mathcal{E}(\boldsymbol{k})=\begin{cases}E(k)=2\left[T(k)\dfrac{N}{2V}G(k)\right]^{1/2}, & \text{for } |\boldsymbol{k}|\leq k_c\,,\\[2ex] \dfrac{\hbar^2k^2}{2m^*}\,, & \text{for } |\boldsymbol{k}|>k_c\,,\end{cases}\qquad(5.2)$$

and $n(\boldsymbol{k})$ is subjected the following restriction

$$\sum_{|\boldsymbol{k}|\neq 0} n(\boldsymbol{k})\leq N\,,\qquad(5.3)$$

where N is the total number of particles. It is remarked here that Eq. (5.3) is the results of the kinematical interactions as was shown in § 4. There remain only "dynamical interactions," i.e., the non-diagonal term in the Hamiltonian. We cannot show that these interactions are very small and can be neglected, and, in fact, these interactions is supposed to modify the energy spectrum (5.2) to approach the Landau spectrum (1.1). Since, however, calculation is very complicated, we do not carry out the calculation here, but proceed the arguments based upon Eq. (5.2). Furthermore, the phonon spectrum (5.2) for $|\boldsymbol{k}|\leq k_c$, may be replaced by $\hbar ck$, if the dispersion can be neglected. Therefore, only the qualitative conclusions can be drawn.

First of all, it is evident that the above model exhibits the Bose condensation because of the restriction (5.3). Furthermore, the transition due to Bose condensation is of the second order. This is due to the form of the spectrum (5.2) which is linear for small k. To prove this, we consider the relation between the energy spectrum and the order of

---

* It might seem to be strange that the number of phonons is restricted. In fact, in the solid state, no restriction is imposed on the number of phonons, although the number of the modes of phonons must be equal to $3N$. But in solids, the coordinates describing phonons are different from ours, Eq. (1.2), and are defined as

$$u_k=\frac{1}{\sqrt{N}}\sum_{j=1}^{N}e^{ikx_j^0}(\boldsymbol{x}_j-\boldsymbol{x}_j^0)\,,$$

where $\boldsymbol{x}_j^0$ is the equilibrium position of j-th atom in the crystal. This is a linear transformation from $\boldsymbol{x}_j$ to $\boldsymbol{u}_k$, and the inverse transformation is possible if and only if the number of the modes is $3N$. If this is the case, no kinematical interactions enter, and the whole system can be described by u_k's. In our case, the inverse transformation of Eq. (1.2) is difficult to find, and it is more convenient to restrict the number of phonons. Moreover, it is due to this difference between above equation and Eq. (1.2) that our phonons can carry the momentum although the phonons in solids do not.

the Bose condensation. In general, let us consider the N particles which have the energy spectrum $\mathcal{E}(k)$ and obey the Bose statistics*.

To investigate the Bose condensation, we may only construct the grand partition function, from which we can get the equation determining the chemical potential μ as a function of the temperature T, the volume V and the number of the particles N. If we get the solution for fixed V and N, in which μ becomes zero below a certain temperature T_c, the Bose condensation occurs at $T=T_c$. The order of the transition is determined by the value of $(\partial\mu/\partial T)_{+T_c}$ and $(\partial^2\mu/\partial T^2)_{+T_c}$, etc. That is, if $(\partial\mu/\partial T)_{+T_c}\neq 0$, the transition is of the second order, and if $(\partial\mu/\partial T)_{+T_c}=0$ and $(\partial^2\mu/\partial T^2)_{+T_c}\neq 0$, then the order becomes third.

Now the equation for μ is given by

$$N=\frac{1}{e^{\alpha}-1}+\frac{V}{8\pi^3}\int_0^\infty 4\pi k^2 dk\frac{1}{e^{\alpha+\beta\mathcal{E}(k)}-1}\,, \qquad (5.4)$$

where $\alpha=-\mu/kT$, and $\beta=1/kT$. In Eq. (5.4), we assume that there is no gap in the excitation energy, that is, $\mathcal{E}(0)=0$ and that $\mathcal{E}(k)$ is a positive function of $|\boldsymbol{k}|=k$ only. The second term of Eq. (5.4) can be written as

$$N_{\text{exc.}}=\frac{V}{2\pi^2}\sum_{n=1}^{\infty}e^{-n\alpha}\int_0^\infty e^{-n\beta\mathcal{E}(k)}k^2dk\,. \qquad (5.5)$$

Here we expand $\mathcal{E}(k)$ in powers of k,

$$\mathcal{E}(k)=a_0k^l(1+a_1k+\cdots)\,, \qquad l>0\,. \qquad (5.6)$$

Substituting Eq. (5.6) into (5.5) and putting $a_0n\beta k^l=y$, we obtain

$$\begin{aligned}N_{\text{exc.}}&=\frac{V}{2\pi^2}\sum_{n=1}^{\infty}\frac{e^{-n\alpha}}{l(n\beta a_0)^{3/l}}\\&\quad\times\int_0^\infty e^{-y(1+a_1(y/n\beta a_0)^{1/l}+\cdots)}y^{(2/l)-1}dy\\&=\frac{V}{2\pi^2}\frac{1}{l}\frac{1}{(\beta a_0)^{3/l}}\sum_{n=1}^{\infty}\frac{e^{-n\alpha}}{n^{3/l}}\\&\quad\times\int_0^\infty e^{-y}y^{(2/l)-1}\left(1+O\left(\frac{y}{n}\right)^{1/l}\right)dy\,.\end{aligned}$$

The integral over y converges because $l>0$. Thus we obtain the equation

$$N_{\text{exc.}}=A_1(T)F_{3/l}(\alpha)+A_2(T)F_{4/l}(\alpha)+\cdots\,, \qquad (5.7)$$

where

$$F_p(\alpha)=\sum_{n=1}^{\infty}\frac{e^{-n\alpha}}{n^p}\,. \qquad (5.8)$$

Now as $\alpha\to 0$, $F_p(\alpha)$ becomes infinite if $p\leq 1$, but remains finite if $p>1$. As is well known, if $N_{\text{exc.}}$, Eq. (5.7), can become infinite, then we always obtain the solution $\alpha>0$, and the Bose condensation does not occur. But, if $N_{\text{exc.}}$ can not become infinite, as $\alpha\to 0$, we obtain the solution in which $\alpha>0$ for $T>T_c$ and $\alpha=0$ for $T\leq T_c$, leading to the Bose condensation. Thus, the condition for Bose condensation to occur is determined by the first term of (5.7) and becomes

$$\frac{3}{l}>1\,, \quad \text{i.e.,} \quad l<3\,. \qquad (5.9)$$

Of course, to determine the condensation temperature T_c all the terms in Eq. (5.7) must be considered.

The order of the transition is determined by the values of the derivatives of α with respect to T when $T\to +T_c$. For $T\geq T_c$, in the equation (5.4) for α, the first term representing the number of the ground state particles can be ignored, and the right hand side of Eq. (5.7) is equal to N. Thus, differentiating Eq. (5.7) with respect to T, and putting $T\to T_c$ and $\alpha\to 0$, we obtain

$$\begin{aligned}0=&\left(\frac{dA_1}{dT}\right)_{T_c}F_{3/l}(0)\\&-A_1(T_c)F_{(3/l)-1}(0)\left(\frac{d\alpha}{dT}\right)_{+T_c}\,,\end{aligned} \qquad (5.10)$$

here we neglect all terms except the first. From Eq. (5.10), we see that if $(3/l)-1\leq 1$, then $(d\alpha/dT)_{+T_c}=0$, and $d\alpha/dT$ is continuous at $T=T_c$ and the transition is of more than third order, and that if $(3/l)-1>1$, then $(d\alpha/dT)_{+T_c}\neq 0$, and $d\alpha/dT$ shows discontinuity at $T=T_c$, the transition being of second order. Thus, we obtain the following relation;

$$\begin{array}{ll}3\leq l & :\ \text{no Bose condensation}\\(3/2)\leq l<3: & \text{Bose condensation, transition}\\ & \text{of third order or more}\\0<l<(3/2): & \text{Bose condensation transition}\\ & \text{of second order}\end{array} \qquad (5.11)$$

In our case, $l=1$ and we obtain the second order transition, while, in the ideal gas, $l=2$ and the transition is of the third order. Thus, our model agrees with the experiment qualitatively.

---

* In our case, the total number of the excitations is not always equal to N. But this does not contradict with the usual statistics of N particles. The right hand side $\sum_{|\boldsymbol{k}|\neq 0}n(\boldsymbol{k})$ of Eq. (5.3) represents the number of excited particles, and the remaining $N-\sum_{|\boldsymbol{k}|\neq 0}n(\boldsymbol{k})$ represents the number of the particles in the ground state.

As was mentioned above the quantitative results are not supposed to have any physical meaning. But we suppose that by adjusting the values of m^* and k_c we can obtain the value of T_c and the specific heat curve which agree with the experimental data.

The temperature dependence of the viscosity coefficient will be investigated in another paper, using the interaction term given in this paper.

§ 6. Conclusions

The two purposes of this paper mentioned in § 1, that is, to connect the excitation theory with the Bose condensation theory, and to write down the interactions among various excitations explicitly, can be achieved by a simple method. The Hamiltonian, derived in § 2 and § 3, is rigorous, and the interactions between phonons are given by $\mathscr{H}'$, Eq. (3.7), and those between phonons and rotons by $\mathscr{H}_{\text{int.}}$, Eq. (3.9), and the roton-roton interactions are included in $\mathscr{H}_{\text{ind.}}$, Eq. (2.7c). The energy spectrum of the excitations has the form, Eq. (5.2), so that our model exhibits the second order transition due to Bose condensation as was shown in § 5. It is noted that this is the result of the elimination of the kinematical interactions. The method of this elimination is very simple and convenient compared with the method of the subsidiary conditions.

As was mentioned in § 2, the interaction energy $G(r)$ between two Helium atoms contains the strong repulsion term of short range, and this makes the Fourier expansion of $G(r)$ impossible. This is completely neglected in the above discussion, and the velocity of sound is determined only by $G(0)=\int G(r)d\boldsymbol{r}$, but does not contain the zero-point energy of Helium atoms. In order to avoid this difficulty about the Fourier expansion of $G(r)$, Bogolyubov[14] proposed that $G(k)$ may be replaced by the matrix element of scattering, and Kanazawa[15] showed that such a procedure was really possible in the method of Bogolyubov. In our case, however, this seems to be impossible. Instead, the following procedure may be employed: We divide the interaction potential $G(r)$ into two parts at the distance r_0,

$$G(r)=G_1(r)+G_2(r)\,,$$

$$G_1(r)=\begin{cases}0 & \text{for} \quad r\leq r_0\,,\\ G(r) & \text{for} \quad r>r_0\,,\end{cases}$$

$$G_2(r)=\begin{cases}G(r) & \text{for} \quad r\leq r_0\,,\\ 0 & \text{for} \quad r>r_0\,.\end{cases}$$

We expand only the first part $G_1(r)$ into Fourier siries and use this to obtain the phonon spectrum and the second part $G_2(r)$ is included in $\mathscr{H}_{\text{ind.}}$, (2.7b). The cut-off length r_0 may be determined from the condition of minimum energy, although this procedure has not such a precise meaning as the usual variation method. Then, the zero-point energy of rotons will affect the phonon spectrum through the value of r_0.

In any way, our model emphasizes the fact the excitation theory can be connected with the Bose condensation theory smoothly, but is not concerned with another characteristic properties of liquid Helium, i.e., the superfluidity below the λ-point, and the reason why the liquid Helium does not solidify under the normal pressure, etc. These are the problems about the ground state of an assembly of Helium atoms.

Nothing is said about the dynamical interactions. One of the effects of these interactions would be the modification of the energy spectrum (5.2) which will probably approach the spectrum Eq. (1.1), proposed by Landau. The other important effect of the interactions will be the scattering of the excitations by each other. The calculation of the cross sections for these scatterings and of the viscosity coefficient of liquid helium will be carried out in another paper.

There remain some ambiguities in our model, for example, about the energy and the wave function of the roton part, and about the smallness of the dynamical interactions. We believe, however, that our model represents the essential properties of liquid helium at least qualitatively.

Finally the value of k_c, introduced in § 2, is determined from the minimization of the ground state energy. In our approximation, the ground state energy of phonon is given by

$$E^0_{\text{phon.}}=\sum_{|k|\leq k_c}\left[\frac{1}{2}E(k)-\frac{N}{2V}G(k)\right]+\frac{N^2}{2V}G(0)\,. \tag{6.1}$$

We do not know about the roton part, but, since the roton energy is supposed to be almost independent of k_c, we may neglect this in the qualitative determination of k_c. In Eq. (6.1), the summand is negative for small k, because there $E(k)\propto k$ and $G(k)\sim G(0)>0$. For large k, $G(k)\to 0$ and the summand is positive, so that the minimum value of $E^0_{\text{phon.}}$ can be obtained by taking as the value of k_c,

$$\frac{1}{2}E(k_c)=\frac{N}{2V}G(k_c)\,. \tag{6.2}$$

Substituting Eq. (3.4) into the above equation, we obtain

$$T(k_c)=\frac{N}{2V}G(k_c)\,. \tag{6.3}$$

We cannot solve this equation exactly because of the lack of the knowledge about $G(k)$, but in the approximation in which the dispersion of sound velocity is neglected, we can set

$$\frac{N}{2V}G(k)\sim\frac{N}{2V}G(0)=\frac{1}{2}mc^2\,.$$

Therefore, from Eq. (6.2) we obtain the value of k_c,

$$\frac{1}{2}\hbar ck_c\approx\frac{1}{2}mc^2\,,\quad k_c\sim 10^8cm^{-1}\,.$$

This gives the right order of magnitude.

The author wishes to express his sincere thanks to Professor A. Harashima and to Professor R. Kubo for their valuable discussions.

Cell Theory of Classical Liquid. Phase Transition between Gas, Liquid and Solid.
Parts I and II.

By Tohru MORITA

Physics Department, Tokyo Institute of Technology

(Received July 4, 1957)

The cell theories of liquid in the past have assumed that the molecules are localized near the centers of cells. In this respect, they may be considered as the theories for solid. In this article, the correlations between the occupations in neighboring cells are taken into account in the degree of Bethe approximation. This improvement of the cell theory is shown to be followed by the transitions between gas, liquid and solid; the liquid and gas states corresponding to the states where the distribution function $\rho^{(1)}(\boldsymbol{r})$ is constant throughout the volume of the system, and the solid state to the state where the distribution function $\rho^{(1)}(\boldsymbol{r})$ is localized near the centers of cells.

The development of the theory is based on the cluster variation method for cooperative phenomena in the cell pair approximation. For the illustrative purpose, the method is first applied to a system of square lattice gas.

The numerical calculations are performed for the oritical point, phase diagram and second Virial coefficient in a very rough approximation, where the intermolecular potential of Lennard-Jones (6–12) type is used.

Part I. Square Lattice Gas

The phase transitions of two-dimensional lattice gases composed of molecules with both hard core and attractive interaction were discussed by Kikuchi[1] and Shimose[2]. Applying the cluster variation method, Kikuchi treated a triangular lattice gas composed of molecules whose potential energy of interaction is infinity between nearest neighbor lattice sites, negative constants between 2nd and 3rd neighbor lattices sites and zero thereafter. Grouping all the lattice sites into three sublattices as shown in Fig. I-1, and assuming that the solid state corresponds to the state where the molecules are more populated in one of sublattices (e.g. ● in Fig. I-1) than the others (○ and ×), he obtained the result that, in order that the stable liquid state exists, it is necessary that the depth of the potential energy of interaction is greater between 3rd neighbor lattice sites than between 2nd neighbor lattice sites. In another approximation, Shimose calculated the equation of state for a square lattice gas composed of molecules whose potential due to a molecule is infinity at the nearest and second neighbor lattice sites, a negative constant at the 3rd and 4th neighbor lattice sites and zero thereafter. Grouping all the lattice sites into four sublattices as shown in Fig. I-2, and assuming that the solid state corresponds to the state where the molecules are more populated in one of sublattices (e.g. ●) than the others (○, × and △), he obtained the result that the stable liquid region would appear.

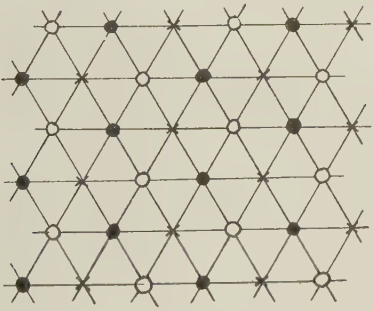

Fig. I-1.

In the following in part I, the square lattice gas, whose constituent molecules have the potential of the type (1′), will be treated by the cluster variation method of approximation[3]. It will then be shown that, if the same premise for the solid state and the same potential as those used by Shimose[2] are adopted, the stable liquid region will not be expected to appear. This problem is, of course, of quite academic nature*. This part may be considered to have the meaning only as the preliminary calculation to part II.

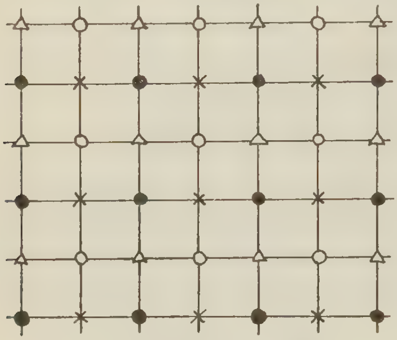

Fig. I–2.

In this part, the part from "Phase Transition of Lattice Gas I" published by the present author in Busseiron Kenkyu No. 106 (March 1957) 30–38 (in Japanese) is translated, which seems to be useful for the development of the following part. Three dimensional lattice gas composed of molecules with both hard core and attractive potential was also discussed by the present author in Busseiron Kenkyu No. 106 (March 1957) 39–50 (in Japanese).

§ 1. Application of the Cluster Variation Method

Let us consider a square lattice with lattice constant $a/2$. Let N indistinguishable particles be on $4L$ lattice sites. Let the potential energy of the system be the sum of contributions from pairs of molecules and the potential energy between two particles, one at $\boldsymbol{r}_s$ and another at $\boldsymbol{r}_t$, be of the form

$$V^{(2)}(\boldsymbol{r}_s, \boldsymbol{r}_t)=V^{(2)}(|\boldsymbol{r}_s-\boldsymbol{r}_t|)\ , \tag{1}$$

$$V^{(2)}(r)\begin{cases}=\infty\ , & r=0,\ a/2,\ \sqrt{2}\,a/2\\ \leqq 0\ , & r\leqq a\\ =0\ , & r\to\infty\ ;\end{cases} \tag{1'}$$

the particles have cores of diameter $\sqrt{2}\,a/2$.

This system may be characterized by the following three conditions: 1) The configuration of the system is described by the configurations of $4L$ lattice sites. 2) The possible configurations x_s for s-th lattice site ($s=1, \cdots, 4L$) are "a particle is present at the site s——$x_s=$p. at s" and "no particle is at the site s——$x_s=$a. at s". 3) The potential energy of the system is, for the configuration $(x_1, \cdots, x_{4L})$,

$$\Phi(x_1, \cdots, x_{4L})=\frac{1}{2}\sum_{s=1}^{4L}\sum_{\substack{t=1\\(s\neq t)}}^{4L} V^{(2)}(x_s, x_t) \tag{2.}$$

$$V^{(2)}(x_s, x_t)=V^{(2)}(\boldsymbol{r}_s, \boldsymbol{r}_t)$$

if both $x_s=$p. at s and $x_t=p$. at t,

$$V^{(2)}(x_s, x_t)=0 \quad \text{if otherwise.} \tag{2'}$$

These conditions allows us to apply directly the formulation of the cluster variation method proposed in CVM to this system.

At first, we have to decide the preserved clusters and the not-preserved clusters. We introduce cells in the lattice as shown in Fig. I-3; a cell consisting of 4 lattice sites. μ-th lattice site in i-th cell will be denoted as $i\mu$ ($i=1, \cdots, L$; $\mu=1, 2, 3, 4$). We divide the clusters, clusters whose constituent lattice sites are conceived either in one or two cells and clusters whose constituent lattice sites are over three or more cells. We adopt the former ones as the preserved and the latter ones as the not-preserved. We will call this way of decision "the cell and cell pair approximation". In this approximation, the function F, whose minimum value is to be taken as the free energy, is written as, according to (CVM-9 and 7)**,

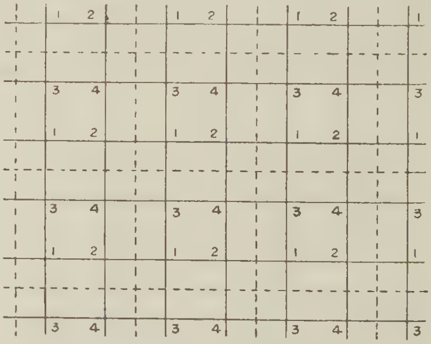

Fig. I–3. The numbers attached to lattice points denote the values of μ.

---

* A possible example of the system, for which the argument of part I will be applied, is the adsorbed monolayer on a crystal surface, when the diameter of the adsorbed molecule is about twice as large as the lattice constant of the crystal surface.

** (CVM–9) means Eq. (9) in CVM[3].

$$
\begin{aligned}
=\sum_{i<j}\sum_{\mu=1}^{4}\sum_{\nu=1}^{4}\rho^{(2)}(x_{i\mu}=\text{p.},x_{j\nu}=\text{p.})V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)\\
+kT\Bigl[\sum_{i=1}^{L}\ln G^{(4)}(i1,i2,i3,i4)\\
+\sum_{i<j}\ln\frac{G^{(8)}(i1,\cdots,i4,j1,\cdots,j4)}{G^{(4)}(i1,\cdots,i4)G^{(4)}(j1,\cdots,j4)}\Bigr].
\end{aligned}
\tag{3}
$$

The approximate equation (3) can be obtained rom another point of view, where the cell is aken as the unit. Then, the system can be haracterized by that: 1) The configuration of he system is described by the configurations f the L cells. 2) The possible configurations x_i of i-th cell are "a particle is present at attice site $i\mu$——p. at $i\mu$", $(\mu=1,2,3,4)$, and "no particle is in the cell i —a. in i". 3) The potential energy of the system is, for he configuration $(x_1,\cdots,x_L)$,

$$
\Phi(x_1,\cdots,x_L)=\frac{1}{2}\sum_{\substack{i=1\\(i\neq j)}}^{L}\sum_{j=1}^{L}V^{(2)}(x_i,x_j)
\tag{4}
$$

$V^{(2)}(x_i,x_j)=V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)$

if both $x_i=$p. at $i\mu$ and $x_j=$p. at $j\nu$,

$=0$ if otherwise. (4′)

In this point of view, if we take all cells and all pairs of cells as the preserved clusters and the others as the not-preserved, then we obtain Eq. (3) for F.

Now, we introduce $\rho^{(\text{cell})}$ (or $\rho^{(4)}$) and $\rho^{(\text{cell pair})}$ (or $\rho^{(8)}$) taking into account of (CVM-10 and 11) as in Tables I and II.

p. at $i\mu$ and a. in j	$\rho^{(1)}(\mu)-\sum_{\nu=1}^{4}\rho^{(2)}(i\mu,j\nu)$
a. in i and p. at $j\nu$	$\rho^{(1)}(\nu)-\sum_{\mu=1}^{4}\rho^{(2)}(i\mu,j\nu)$
a. in i and a. in j	$1-2\rho+\sum_{\mu=1}^{4}\sum_{\mu=1}^{4}\rho^{(2)}(i\mu,j\nu)$

$g'^{(2)}(i\mu,j\nu)=g^{(2)}(\mu,\nu;\boldsymbol{r}_{i1}-\boldsymbol{r}_{j1})$

By using these tables with (CVM-6), (3) becomes

$$
\begin{aligned}
\frac{F}{LkT}=&\frac{1}{2kT}\sum_{\substack{j=1\\(j\neq i)}}^{L}\sum_{\mu=1}^{4}\sum_{\nu=1}^{4}\rho^{(1)}(\mu)\rho^{(1)}(\nu)g^{(2)}(i\mu,j\nu)V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)\\
&+\sum_{\mu=1}^{4}\rho^{(1)}(\mu)\ln\rho^{(1)}(\mu)+(1-\rho)\ln(1-\rho)\\
&+\frac{1}{2}\sum_{\substack{j=1\\(j\neq i)}}^{L}\Bigl\{\sum_{\mu=1}^{4}\sum_{\nu=1}^{4}\rho^{(1)}(\mu)\rho^{(1)}(\nu)g^{(2)}(i\mu,j\nu)\ln g^{(2)}(i\mu,j\nu)\\
&+\sum_{\mu=1}^{4}\rho^{(1)}(\mu)\Bigl[1-\sum_{\nu=1}^{4}\rho^{(1)}(\nu)g^{(2)}(i\mu,j\nu)\Bigr]\ln\frac{1-\sum_{\nu=1}^{4}\rho^{(1)}(\nu)g^{(2)}(i\mu,j\nu)}{1-\rho}\\
&+\sum_{\nu=1}^{4}\rho^{(1)}(\nu)\Bigl[1-\sum_{\mu=1}^{4}\rho^{(1)}(\mu)g^{(2)}(i\mu,j\nu)\Bigr]\ln\frac{1-\sum_{\mu=1}^{4}\rho^{(1)}(\mu)g^{(2)}(i\mu,j\nu)}{1-\rho}\\
&+\Bigl[1-2\rho+\sum_{\mu=1}^{4}\sum_{\nu=1}^{4}\rho^{(1)}(\mu)\rho^{(1)}(\nu)g^{(2)}(i\mu,j\nu)\Bigr]\ln\frac{1-2\rho+\sum_{\mu=1}^{4}\sum_{\nu=1}^{4}\rho^{(1)}(\mu)\rho^{(1)}(\nu)g^{(2)}(i\mu,j\nu)}{(1-\rho)^2}\Bigr\}.
\end{aligned}
\tag{5}
$$

$\rho^{(1)}(\mu)$ and $g^{(2)}(i\mu,j\nu)$ are to be determined so as to minimize this equation (5). It is easily seen that $g^{(2)}(i\mu,j\nu)$ is zero when $V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)=\infty$ and unity when between two cells i and j $V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)=0$ for any of $\mu=1,\cdots,4$ and any of $\nu=1,\cdots,4$.

In the next section, we restrict the variational functions $\rho^{(1)}$ and $g^{(2)}$ and proceed the approximate calculation.

§ 2. Approximate Calculation

In a quite rough approximation, we restrict the variational functions in the form

$$g^{(2)}(i\mu, j\nu)=\begin{cases} 0 & \text{if } V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)=\infty \\ 1 & \text{if otherwise}\,, \end{cases} \tag{6}$$

$$\rho^{(1)}(1)=\frac{\rho}{4\cosh^2\beta}e^{2\beta},\quad \rho^{(1)}(2)=\rho^{(1)}(3)=\frac{\rho}{4\cosh^2\beta},$$

$$\rho^{(1)}(4)=\frac{\rho}{4\cosh^2\beta}e^{-2\beta}; \tag{7}$$

the only parameter β is to be determined so as to minimize F. Substituting these into (5), we obtain $\beta=0$ as one of roots for $\partial F/\partial\beta=0$, and calculating $(\partial^2F/\partial\beta^2)_{\beta=0}$, we find that $\beta=0$ corresponds to the minimum at higher temperatures than T_1 given by

$$\begin{aligned}-\frac{1}{kT_1}(4\varphi_a-8\varphi_c)=&\frac{4}{\rho_1}-5-\frac{1}{3}\\ &+\frac{1}{3}\frac{1}{1-\frac{3}{4}\rho_1}+\frac{2}{1-\frac{1}{2}\rho_1}\\ &-2\ln\left(1-\frac{1}{2}\rho_1\right)+2\ln\left(1-\frac{3}{2}\rho_1\right)\\ &-\ln\left(1-\frac{3}{4}\rho_1\right)+\ln\left(1-\frac{5}{4}\rho_1\right)\end{aligned} \tag{8}$$

and to the maximum at the lower temperatures; where

$$4\varphi_a\equiv\sum_{j=1}^{L}{}^{*}\,V^{(2)}(|\boldsymbol{r}_{i1}-\boldsymbol{r}_{j1}|)\,, \tag{9a}$$

$$8\varphi_b\equiv\sum_{j=1}^{L}{}^{*}\,[V^{(2)}(|\boldsymbol{r}_{i1}-\boldsymbol{r}_{j2}|)+V^{(2)}(|\boldsymbol{r}_{i1}-\boldsymbol{r}_{j3}|)]\,, \tag{9b}$$

$$8\varphi_c\equiv\sum_{j=1}^{L}{}^{*}\,V^{(2)}(|\boldsymbol{r}_{i1}-\boldsymbol{r}_{j4}|)\,, \tag{9c}$$

where * on the summations means that in the summations j for which $V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}|)=\infty$ should be omitted.

When $\beta\neq0$, one of sublattices (e.g. $\mu=1$) is more populated than the others ($\mu=2, 3, 4$) and the state may be considered as the solid state. On the contrary, if $\beta=0$, then $\rho^{(1)}(1)=\rho^{(2)}(2)=\rho^{(1)}(3)=\rho^{(1)}(4)$ and this state may be considered as the fluid state. The transition between these states is given by Eq. (8), which is drawn in Fig. I-4. The quantities for fluid state can easily be calculated; for instance the critical point is given by

$$\rho_c=0.332\,,\qquad 1/\rho_c=3.01\,,$$

$$\frac{kT_c}{-(\varphi_a+2\varphi_b+2\varphi_c)}=0.1380\,. \tag{10}$$

The potential used by Shimose is $\varphi_a=\varphi_b=-$ $\varphi_c=0$; for these values $kT_c=0.414$, this crit cal value is also plotted in Fig. I-4.

This figure I-4 shows that from our ap proximate calculation we cannot expect th appearance of the stable liquid region.

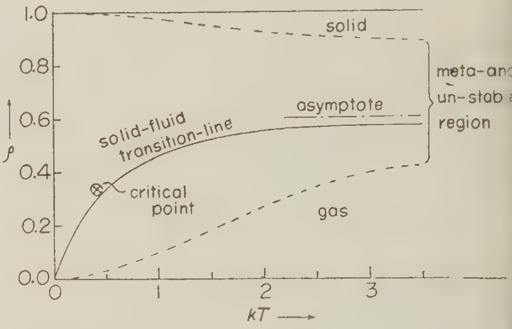

Fig. I-4. Phase Diagram. ($\varphi_a=\varphi_b=-1$, $\varphi_c=0$; th dotted lines are schematically drawn.)

Part II. Classical Liquid

In this part, we translate the calculation c the previous part to the case where the num ber of the lattice sites in a cell is very large and then we make this number tend t infinity.

§ 1. Application of the Cluster Variatio Method

The system considered in this part is suc that N particles are interacting with eac other by Lennard-Jones (6–12) potential in volume V.

At first, we consider the case where th particles constituting the system have har cores of diameter σ. Let us divide the volum V of the system into L cells in such a wa that the diameter of any of the L cells doe not exceed σ. Moreover, let each cell b divided into s volume elements. Then, thi system may be characterized by that: 1) Th configuration of the eystem is described b the configurations of sL volume elements. 2 The possible configuration for a volume ele ment is either "a particle is present in it or "no particle is in it". 3) The potentia energy of the system is the sum of potential between pairs of volume elements, and th potential between a pair of volume element is $V^{(2)}(r)$, r being the distance between th volume elements, when the configurations c both volume elements are "a particle is pre sent in it" and is zero otherwise. In thi ase, we need an additive term (CVM-12) for ne function F, whose minimum is to be aken as the free energy of the system: This erm is calculated by putting $n(x_i=$" a particle s present in i "$)=u_i$, u_i being the volume of ne volume element i, $(i=1, \cdots, sL)$, and $(x_i=$" no particle is in i "$)=1$. Applying the luster variation method in the cell and cellair approximation, we obtain an expression or F analogous to (I-3)*. This equation is btained form another point of view where he cell is taken as the unit, just as is done n part I. In this point of view, the system s characterized by that: 1) The configuration f the system is described by the configuraions of L cells. 2) The possible configurations f cell i are " a particle is present in volume lement $i\mu$——p. in $i\mu$ " $(\mu=1, \cdots, s)$ and " no article is in the cell i -a. in i ". 3) The otential energy of the system is, for the coniguration $(x_1, \cdots, x_L)$,

$$\Phi(x_1, \cdots, x_L)=\frac{1}{2}\sum_{\substack{i=1\\(i\neq j)}}^{L}\sum_{j=1}^{L} V^{(2)}(x_i, x_j) \qquad (1)$$

$$V^{(2)}(x_i, \cdots x_j)=V^{(2)}(|\boldsymbol{r}_{i\mu}-\boldsymbol{r}_{j\nu}-\boldsymbol{R}_{ij}|)$$
$$\text{if both } x_i=\text{p. in } i\mu \text{ and } x_j=\text{p. in } i\nu\,,$$
$$=0 \qquad \text{if otherwise}\,, \qquad (1')$$

where $\boldsymbol{r}_{i\mu}$ is the vector from the center of cell i to that of the volume element $i\mu$ and $\boldsymbol{R}_{ij}$ is the vector from the center of cell i to that of cell j. The additive term to F is calculated by taking $n(x_i=\text{p. in } i\mu)=u_{i\mu}$ and $n(x_i=\text{a. in } i)=1$.

We take as L cells decahedrons of equal volume $u=V/L$, then the centers of cells constitute a face centered cubic lattice, the distance between nearest neighbor lattice sites being $(u/\sqrt{2})^{1/3}$. Denoting a volume element by $d\boldsymbol{r}$, where $\boldsymbol{r}$ is the vector drawn from the cell center, we take the probabilities for the configurations of cell and cell pair as in Tables I and II.

Table I.

configuration of cell	its probability
present in $d\boldsymbol{r}$ at $\boldsymbol{r}$	$\rho^{(1)}(\boldsymbol{r})d\boldsymbol{r}$, $(\boldsymbol{r}$ in $u)$
absent in the cell	$1-\rho$, $\rho\equiv\int^{u}\rho^{(1)}(\boldsymbol{r})d\boldsymbol{r}$

Table II.

configuration of cell pair (i, j)	its probability
p. in $d\boldsymbol{r}_i$ at $\boldsymbol{r}_i$ and p. in $d\boldsymbol{r}_j$ at $\boldsymbol{r}_j$	$\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})d\boldsymbol{r}_i d\boldsymbol{r}_j=\rho^{(1)}(\boldsymbol{r}_i)\rho^{(1)}(\boldsymbol{r}_j)g^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})d\boldsymbol{r}_i d\boldsymbol{r}_j$
p. in $d\boldsymbol{r}_i$ at $\boldsymbol{r}_i$ and a. in j	$\left[\rho^{(1)}(\boldsymbol{r}_i)-\int^{uj}\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})d\boldsymbol{r}_j\right]d\boldsymbol{r}_i$
a. in i and p. in $d\boldsymbol{r}_j$ at $\boldsymbol{r}_j$	$\left[\rho^{(1)}(\boldsymbol{r}_j)-\int^{ui}\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})d\boldsymbol{r}_i\right]d\boldsymbol{r}_j$
a. in i and a. in j	$1-2\rho+\int^{ui}\int^{uj}\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})d\boldsymbol{r}_i d\boldsymbol{r}_j$

Using these tables, we make the function F. In the limit of $s\rightarrow\infty$, the function F becomes

$$\begin{aligned}\frac{F}{LkT}=&\frac{1}{2kT}\sum_{\substack{j=1\\(j\neq i)}}^{L}\int^{ui}\int^{uj}d\boldsymbol{r}_i d\boldsymbol{r}_j V^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})\\&+\int^{u}d\boldsymbol{r}\rho^{(1)}(\boldsymbol{r})\ln\rho^{(1)}(\boldsymbol{r})+(1-\rho)\ln(1-\rho)\\&+\frac{1}{2}\sum_{\substack{j=1\\(j\neq i)}}^{L}\Bigg[\int^{ui}\int^{uj}d\boldsymbol{r}_i d\boldsymbol{r}_j\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})\ln g^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})\\&+\int^{ui}d\boldsymbol{r}_i\left(\rho^{(1)}(\boldsymbol{r}_i)-\int^{uj}d\boldsymbol{r}_j\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})\right)\ln\frac{1-\int^{uj}d\boldsymbol{r}_j\rho^{(1)}(\boldsymbol{r}_j)g^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})}{1-\rho}\\&+\int^{uj}d\boldsymbol{r}_j\left(\rho^{(1)}(\boldsymbol{r}_j)-\int^{ui}d\boldsymbol{r}_i\rho^{(2)}(\boldsymbol{r}_{\cdot i}\ \boldsymbol{r}_j; \boldsymbol{R}_{ij})\right)\ln\frac{1-\int^{ui}d\boldsymbol{r}_i\rho^{(1)}(\boldsymbol{r}_i)g^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})}{1-\rho}\\&+\left(1-2\rho+\int^{ui}\int^{uj}d\boldsymbol{r}_i d\boldsymbol{r}_j\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij})\right)\ln\frac{1-2\rho+\int^{ui}\int^{uj}d\boldsymbol{r}_i d\boldsymbol{r}_j\rho^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j: \boldsymbol{R}_{ij})}{1-\rho}\Bigg], \quad (2)\end{aligned}$$

---

* (I-3) means Eq. (3) of part I.

[illegible] and [illegible] and $L=V/u$ are determined so as to make this function F a minimum. As t $g^{(2)}$, the statement under Eq. (I-5) is valid. The variation by $g^{(2)}$ gives

$$e^{-V^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})/kT}=\frac{\rho^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})\left(1-2\rho+\int^{ui}\int^{uj}d\boldsymbol{r}_i\,d\boldsymbol{r}_j\rho^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})\right)}{\left(\rho^{(1)}(\boldsymbol{r}_i)-\int^{uj}d\boldsymbol{r}_j\rho^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})\right)\left(\rho^{(1)}(\boldsymbol{r}_j)-\int^{ui}d\boldsymbol{r}_i\rho^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})\right)},\quad (3$$

This is the generalization of the approximate formula which is the basis of the Bethe or quasi-chemical approximation[4].

In the above arguments, we have proceeded the discussion under the restriction that the diameter of a cell does not exceed σ. When the diameter of a cell is allowed to exceed σ, we have to take into account the probability that two particles are present in a cell in addition. However, if the probabilities of such configurations are negligible, we may consider these probabilities to be zero before the variation is taken; which will affect the result very little. And with this procedure, the function F to be minimized becomes the form of Eq. (2) again. In conclusion, if the cell size is not very large compared with the diameter of a particle, we may calculate the free energy of the system using Eq. (2) for F. Analogously, when, even if the particles do not have the hard cores, the interparticle potential is rather singular and the probability that two or more particles are present in a cell is negligible, we may calculate the free energy by using (2).

We will apply Eq. (2) to the case of Lennard-Jones (6–12) potential

$$V^{(2)}(r)=4\left(\frac{1}{r^{12}}-\frac{1}{r^{6}}\right). \qquad (4)$$

In equation (2), if we put $g^{(2)}=1$, then only the first three terms are retained, which is just the form from which Mayer and Careri[5] started their variational calculation. This approximation may be called "the cell approximation" in our scheme of development. Moreover, if $\rho=1$, it reduces to the equation introduced by Kirkwood[6]. In our scheme, the hole theory of liquid[7], in its features, may be considered as the approximation where $g^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})$ is taken in the form $g^*(\boldsymbol{r}_i)g^*(\boldsymbol{r}_j)$, $g^*(\boldsymbol{r})=\alpha\{\rho^{(1)}(\boldsymbol{r})\}^{\beta}$, α and β being constants, when i and j are neighboring cells and taken unity otherwise. When we take $g^*(\boldsymbol{r})=c^{1/2}$, c: constant to be determined so as to minimize F, the obtained form of F is also obtained i in the theory of Levine, Mayer and Aroeste[8] the rigorous grand partition function ψ_0 to a lattice gas is replaced by the function whic is obtained by applying Bethe-Fowler approx mation. It is my opinion that with the ap proximation of the form $g^{(2)}(\boldsymbol{r}_i,\boldsymbol{r}_j;\,\boldsymbol{R}_{ij})=$ $g^*(\boldsymbol{r}_i)g^*(\boldsymbol{r}_j)$ the localization of $\rho^{(1)}(\boldsymbol{r})$ near th centers of cells is inevitable, and as the co sequence we cannot expect the transition be tween solid and liquid or gas. It is to b noted that when we start with "the cell an point pair approximation" then the last thre terms in the sum of the fourth term of drop, and when we start with "the point an point pair approximation", then the third term drops in addition.

In our approximation, as u is taken to b smaller, the number of the preserved cluster is reduced and the evaluation of entropy term will be worse. So, we will restrict the valu of u so as not to become too small and deter mine $\rho^{(1)}$, $g^{(2)}$ and u so as to minimize th function F.

As to the result of the variation, it i expected from the calcuations for lattic gases*, that two regions will appear: th "fluid" region where $\rho^{(1)}(\boldsymbol{r})=1/v$ (constan independent of $\boldsymbol{r}$) at large specific volume and high temperature kT and the "solid region where $\rho^{(1)}(\boldsymbol{r})$ is localized near the cente of cell at small v and low kT. We will henc take up two sets of variational functions wit one parameter, each corresponding to one o these two regions, and adopt the smaller o the two minimum values for F as the ap proximate value of the free energy.

§ 2. Approximate Calculations

2a. Fluid Region. The variational func tions corresponding to the fluid state ar chosen to be

$$\rho^{(1)}(\boldsymbol{r})=1/v\,,\quad v=V/N=u/\rho \qquad (5$$

---

* Part I and several papers cited there.

$$g^{(2)}(\boldsymbol{r}_i, \boldsymbol{r}_j; \boldsymbol{R}_{ij}) = g^{(2)}(|\boldsymbol{r}_i - \boldsymbol{r}_j - \boldsymbol{R}_{ij}|) \qquad (6)$$

$$g^{(2)}(\boldsymbol{r}) = 0 \quad r < a\,, \qquad = 1 \quad r > a \qquad (6')$$

in the same degree of approximation as used in Part I. Substituting these into the right-hand side of Eq. (2), retaining the contributions between nearest neighbor cells only in the sum of the fourth term and estimating the integrals in the last three terms in the sum of the fourth term in an approximate way, we obtain, for $f \equiv F/N$,

$$\begin{aligned} \frac{f}{kT} &= \frac{1}{2}\,\frac{\rho}{ukT}\int_a^\infty V^{(2)}(r)\,4r^2 g\left(\frac{r}{a}, \xi\right)dr \\ &\quad + \ln\frac{\rho}{u} + \frac{1}{\rho}(1-\rho)\ln(1-\rho) \\ &\quad + 12(1-\gamma\rho)\ln\frac{1-\gamma\rho}{1-\rho} \\ &\quad + \frac{6}{\rho}(1-2\rho+\gamma\rho^2)\ln\frac{1-2\rho+\gamma\rho^2}{(1-\rho)^2} \end{aligned} \qquad (7)$$

where

$$\gamma u \equiv \int^{u_j} g^{(2)}(\boldsymbol{r}_i = 0, \boldsymbol{r}_j; |\boldsymbol{R}_{ij}| = (u/\sqrt{2})^{1/3})\,d\boldsymbol{r}_j \qquad (8)$$

and $\xi \equiv a^3/u$; γ being the function of ξ only. $g(r/a, \xi)$ is the factor due to the fact that there cannot be two particles in a single cell at a time. Substituting (4) into (7), assuming ξ to be constant and approximating that $g(r/a, \xi) \equiv 1$, we find that the value of u which minimize f/kT is given by

$$\begin{aligned} \frac{2}{\xi^2 u^2} &= 1 + \left\{1 - \frac{6kT}{4\sqrt{2}\,\pi}\left[\frac{1}{\rho} - \frac{11}{\rho^2}\ln(1-\rho)\right.\right. \\ &\quad + 12\gamma\ln(1-\gamma\rho) \\ &\quad \left.\left. + \left(\frac{6}{\rho^2} - 6\gamma\right)\ln(1-2\rho+\gamma\rho^2)\right]\right\}^{1/2}. \end{aligned} \qquad (9)$$

The equation of state is obtained from (7) and (9) to be

$$\frac{pv}{kT} = \frac{1}{vkT}\,\frac{16\pi}{9\xi u}\left(\frac{2}{\xi^2 u^2} - 3\right) + 1\,. \qquad (10)$$

In these equations, on the one hand, we have retained the correlations between nearest neighbor cells only, which is justified if ξ is small, and, on the other hand, we have put $g(r/a; \xi) \equiv 1$, which is justified if ξ is large. As the point of compromise, we may estimate that $\xi \fallingdotseq \sqrt{2}$ from intuition; when $\xi = \sqrt{2}$, a is equal to the distance between centers of neighboring cells. In the following, we use for numerical calculations

$$\xi = \sqrt{2} \quad \text{and} \quad \gamma = 0.594\,. \qquad (11)$$

The critical values obtained are

$kT_c = 1.31$, $v_c = 2.77$, $p_c = 0.168$, $p_c v_c / kT_c = 0.354$,

which are to be compared with the experimental values for argon:

$kT_c = 1.26$, $v_c = 3.14$, $p_c = 0.117$, $p_c v_c / kT_c = 0.291$.

In Figs. II-1 and II-2, the pressure and density under liquid-gas equilibrium calculated by using (9) and (10) are drawn.

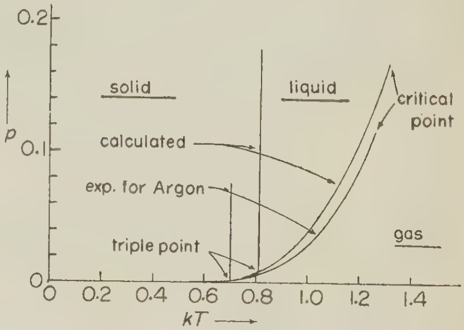

Fig. II-1. Phase Diagram (p-kT).

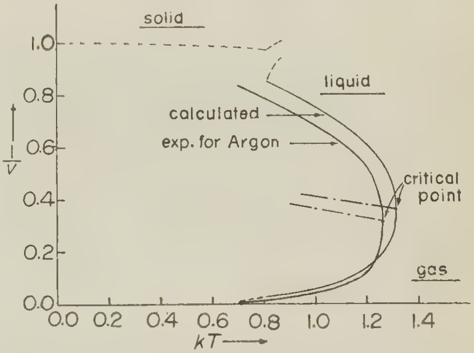

Fig. II-2. Phase Diagram ($1/v$-kT).

In the limit of $v \to \infty$, (10) and (9) reduce to

$$\frac{pv}{kT} = 1 + \frac{B}{v} \qquad (12)$$

$$B = \frac{1}{kT}\,\frac{16\pi}{9u\xi}\left(\frac{2}{\xi^2 u^2} - 3\right) \qquad (13)$$

$$\frac{2}{\xi^2 u^2} = 1 + \sqrt{1 + \frac{3\sqrt{2}}{4\pi}(6.5 - 6\gamma)kT}\,. \qquad (14)$$

The second Virial coefficient B calculated with $\gamma = 0.594$ is compared with the rigorous value in Fig. II-3*.

---

* If we determine the value of γ so that the value of B at high temperature ($kT = 400$) may fit with the rigorous value, we obtain $\gamma = 0.639$. The curve of B with this γ is also drawn in Fig. II-3. Using $\gamma = 0.639$ and $\xi = 1.3042$, we obtain for the critical values

$kT_c = 1.38$, $v_c = 2.95$, $p_c = 0.179$, $p_c v_c / kT_c = 0.382$.

2b. Solid Region. The variational functions corresponding to the solid state are chosen to be

$$\rho^{(1)}(\boldsymbol{r})=\left(\frac{6}{2^{1/3}\pi y}\right)^{3/2} e^{-6r^2/2^{1/3}y}\ , \qquad (15)$$

$$g^{(2)}(\boldsymbol{r}_i,\ \boldsymbol{r}_j;\ \boldsymbol{R}_{ij})=1\ , \qquad (16)$$

$$u=v\equiv x^3 \quad \text{or} \quad L=N\ . \qquad (17)$$

Of course, it might seem to be desirable to choose the variational functions with more parameters, e.g. those used by Mayer and Careri[5] or those analogous to Levine, Mayer and Aroeste's[8]. However, at the density of solid these reduce to the one we have chosen, which is seen from the Table I in Mayer and Careri's paper, so it is satisfactory to calculate with our variational functions.

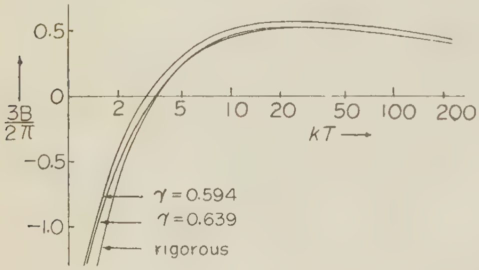

Fig. II-3. Second Virial Coefficient.

Substituting (15)–(17) into (2) and adopting such approximations in the first term that the potential energy is replaced by Morse type

$$V^{(2)}(r)=e^{-12[(r/2^{1/6})-1]}-2e^{-6[(r/2^{(1/6)})-1]} \qquad (4')$$

when the contributions from nearest neighbor cells are calculated and by the values for the distance between the centers of cells when the contributions of the further apart cells are calculated, we obtain

$$\frac{f}{kT}=\frac{f_1}{kT}+\frac{1}{kT}\left(\frac{0.06594}{v^4}-\frac{2.45392}{v^2}\right) \qquad (18)$$

$$\frac{f_1}{kT}=\frac{6}{kT}[(1-2xy)e^{12x^2y-12x+12}-2(1-xy)e^{3x^2y-6x+6}]$$

$$-\frac{3}{2}\ln y+\frac{3}{2}\ln\frac{6}{2^{1/3}\pi e}-3\ln x \qquad (18')$$

where y is determined by

$$\frac{kT}{8xy}=-[1-6x(1-2xy)]e^{12x^2y-12x+12}$$

$$+[1-3x(1-xy)]e^{3x^2y-6x+6}\ , \qquad (19)$$

which has been obtained from (18) by taking $\partial(f/kT)/\partial y=0$.

f/kT from (7) and (9) and from (18) and (19) are drawn in Fig. II-4 for $kT=0.7$, 0.8 and 0.85. The lower of these two is taken to give the approximate value for the free energy. From this figure, the values for solid and liquid equilibrium with $p=0$ are read to be

$$kT_{\text{tr.}}=0.81\ ,\quad v_{\text{tr. solid}}=1.03\ ,\quad v_{\text{tr. liquid}}=1.17$$

which may be compared with the values for melting point of argon ($p=0.0024$)

$$kT_{\text{m.}}=0.699\ ,\quad v_{\text{m. solid}}=1.07\ ,\quad v_{\text{m. liquid}}=1.17\ .$$

The equilibrium curves between solid and liquid and also between solid and gas are drawn in Fig. II-1 and II-2, in a very rough approximation; the values being taken from Fig. II-4.

Though the calculations have been very rough, our cell theory may be said to be the theory for gas, liquid and solid, while the cell theories of liquid in the past to be rather theories for solid and unstable solid. Considering the roughness of the approximations used, numerical values obtained may well be said to be generally in good agreement with the experimental values.

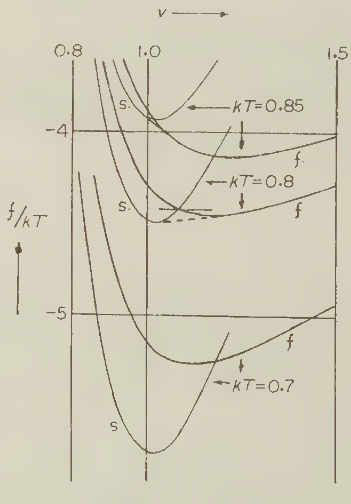

Fig. II-4.

The author wishes to express his cordial thanks to Prof. A. Harasima for his continual guidance and kind inspection of the manuscript and to Dr. K. Hiroike of this Institute and Dr. T. Usui of Tokyo University for their helpful discussions and criticisms.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 11, NOVEMBER, 1957

Statistical-Mechanical Theory of Irreversible Processes. II. Response to Thermal Disturbance

By Ryogo KUBO, Mario YOKOTA*
Department of Physics, University of Tokyo
and Sadao NAKAJIMA
Physical Institute, Nagoya University.

(Received August 3, 1957)

The possibility is examined to give rigorous expressions for kinetic coefficients such as heat conductivity, diffusion constant, thermoelectric power and so on which relate the flow of a certain kind to the generalized forces of thermal nature. We take here as the fundamental assumption Onsager's assumption that the average regression of spontaneous fluctuation of macroscopic variables follows the macroscopic physical laws. The kinetic coefficient G_{jl} appearing in the phenomenological equation, $\dot{\alpha}_j=\sum G_{jl}\,(\partial S/\partial\alpha_l)$ is shown then to be expressed as

$$G_{jl}=(k\beta)^{-1}\int_0^\infty d\tau\int_0^\beta <\dot{\alpha}_l(-i\hbar\lambda)\,\dot{\alpha}_j\,(\tau)>d\lambda$$

where k is the Boltzmann constant and $\beta=1/kT$. This is the same type of formula as we have for kinetic coefficients for mechanical disturbances (Kubo, J. Phys. Soc. **12** (1957) 570). The theory is illustrated for the example of electronic transport phenomena.

§ 1. Introduction

In the preceding paper by one of the present authors[1] a general theory has been developed for the calculation of kinetic coefficients such as electric conductivity and complex susceptibility in periodic field. It was shown that these kinetic coefficients are expressed in terms of time fluctuation of appropriate internal variables of the system. This conclusion was obtained by a perturbational calculation of linear response of the system to the external disturbance which is explicitly involved in the Hamiltonian of the system. We shall call in the following such disturbance as *mechanical*.

The mechanical disturbance is controlled by the observer in a mechanical way and the interaction of the system with the outer body which is directly controlled can be expressed by an additional perturbation energy which perturbs the natural motion of the system. There exists another kind of outer disturbances which will be called *thermal* disturbances. We are dealing with this kind of disturbance when we observe a non-equilibrium system in which temperature, pressure or concentration of particles is changing spacially or temporally. Thermal disturbances can not be expressed by definite perturbation energy in an unambiguous way.

---

* Now at the Research Institute for Fundamental Physics, University of Kyoto, Kyoto.

Now the question arises if it is possible to give similar expressions of the kinetic coefficients for thermal disturbances as those obtained for the mechanical disturbances. The answer should be yes, as we anticipate from the fact that the whole theory developed in I is a sort of generalization of the Einstein relation which means the conductivity is related to the diffusion constant. The aim of the present paper is to give a physical argument to justify this anticipation.[2] We shall do this by following the line of logics used by Onsager[3] in his monumental work on the reciprocity theorem. The general idea will be discussed in the first two sections. This will be further illustrated in the last section by the example of electron transport phenomena. The exact expressions are given for the kinetic coefficients appearing in the linear relations connecting electric and heat currents with the gradient of electrochemical potential and temperature.

§ 2. Application of Onsager's Assumption. Classical Case

In order to derive the generalized reciprocity law, Onsager[3] made the fundamental assumption;

(*A*) *The average behavior of fluctuation of a physical quantity in an aged system is governed by the macroscopic physical law which governs the macroscopic change of the corresponding macroscopic variable.*

This assumption is easily understood by a simple example. We may have local and temporal fluctuation of the temperature distribution in a system in thermal equilibrium. This fluctuation will decay in time on the average, following the Fourier law of heat conduction. We shall call this *Onsager's assumption.*

This will be expressed mathematically in the following way. Let $\alpha_j (j=1, 2, \cdots n)$ be a set of macroscopic variables of a system which we observe. These variables are considered as stochastic variables. We further introduce the variable,

$$\alpha_j(t+\Delta t|\alpha')\,,$$

which is defined as the stochastic variable α_j at the time point $t+\Delta t$ when the observed values of $(\alpha_1, \cdots, \alpha_n)$ at the time t are specified to $(\alpha_1', \cdots, \alpha_n')$. Now the assumption asserts that the relation,

$$\overline{\alpha_j(t+\Delta t|\alpha')}-\alpha'_j=\sum_k G_{jk}\frac{\partial S}{\partial \alpha'_k}\Delta t\,, \qquad (2.1$$

holds for a time interval Δt which is short i macroscopic sense but is sufficiently long o microscopic scale. In Eq. (2.1) $\overline{\alpha_j(t+\Delta t|\alpha')}$ i the average of $\alpha_j(t+\Delta t|\alpha')$ for all possibl initial states at the time t, which are com patible with the prescribed values α' at t On the right hand side of the equation, S i the entropy which is considered as the func tion of the variables α_1', α_2', $\cdots$ α_n', so tha $\partial S/\partial\alpha'_j$ multiplied by the temperature T i the generalized force which drives th variables α_1', $\cdots$ α_n' to change in macroscopi way. The constants G_{jk} are the macroscopic coefficients which correlate the motion of α to the driving forces. As far as we confin ourselves to those cases where the deviatio from equilibrium is small enough, we general ly expect the existence of linear relation between the average velocity of regression o α_j' and the driving forces.[3][4] In such case G_{jk}'s are simply constants in which we ar now interested.

Onsager obtained his celebrated law of re ciprocity from this assumption and the prin ciple of microscopic reversibility by showin that

$$\langle\alpha_j(t+\Delta t)\alpha_l(t)\rangle-\langle\alpha_j(t)\alpha_l(t)\rangle=-kG_{jl}\Delta t \qquad (2.2$$

where k is the Boltzmann constant and $\langle$ means the average over the equilibrium en semble.

Now we see that Onsager's assumptio provides us, besides the general proof of re ciprocity, a method of calculating G_{jl} in term of the time correlation of fluctuating variable α if the correlation can be calculated.

This is essentially the way of our reason ing employed in the present paper. In th preceding paper[1] we pursued the dynamica response of the system to a mechanical oute disturbance to derive the admittance i general, which is expressed as the Fourie component of time fluctuation of correspond ing physical quantities (fluctuation-dissipatio theorem).[1][5] Onsager's assumption is rathe a consequence of that argument. But, no we reverse our standpont, and start fro Eq. (2.1), that is the assumption (A).

In order to obtain a concrete expression o the coefficient G_{jl}, we rewrite Eq. (2.2) as follows.

$$
\begin{aligned}
G_{jl} &= -\frac{1}{k\Delta t}\langle \alpha_j(t+\Delta t)\alpha_l(t)-\alpha_j(t)\alpha_l(t)\rangle \\
&= +\frac{1}{k\Delta t}\int_0^{\Delta t} dt' \int_0^{t'} \langle \dot\alpha_j(t+\tau)\dot\alpha_l(t)\rangle\, d\tau \\
&= \frac{1}{k}\int_0^{\Delta t}\left(1-\frac{\tau}{\Delta t}\right)\langle \dot\alpha_j(t+\tau)\dot\alpha_l(t)\rangle\, d\tau \qquad (2.3)
\end{aligned}
$$

In this transformation we used the relation,

$$\frac{d^2}{d\tau^2}\langle \alpha_j(t+\tau)\alpha_l(t)\rangle = -\langle \dot\alpha_j(t+\tau)\dot\alpha(t)\rangle\,, \qquad (2.4)$$

which follows from the condition of stationary process,

$$
\begin{aligned}
\langle \alpha_j(t)\alpha_l(t')\rangle &= \langle \alpha_j(t+t_0)\alpha_l(t'+t_0)\rangle \\
&= \langle \alpha_j(t-t')\alpha_l(0)\rangle \\
&= \langle \alpha_j(0)\alpha_l(t'-t)\rangle\,, \qquad (2.5)
\end{aligned}
$$

and the assumption* that

$$\langle \dot\alpha_j\alpha_l\rangle = -\langle \alpha_j\dot\alpha_l\rangle = 0\,. \qquad (2.6)$$

Eq. (2.3) can further be written as

$$
\begin{aligned}
G_{jl} &\simeq \frac{1}{k}\int_0^\infty \langle \dot\alpha_j(t+\tau)\dot\alpha_l(t)\rangle\, d\tau \\
&= \frac{1}{k}\int_0^\infty \langle \dot\alpha_j(t)\dot\alpha_l(0)\rangle\, dt\,, \qquad (2.7)^{**}
\end{aligned}
$$

provided that the correlation time of $\dot\alpha_j$ and $\dot\alpha_l$ is short enough compared with that of α_j and α_l which is governed by the macroscopic law and is measured by

$$\tau_{\text{macro}} = \langle \alpha_j\alpha_l\rangle / kG_{jl}\,. \qquad (2.8)$$

As we see from Eq. (2.2), Eq. (2.7) is just the type of expression which we want to discuss in the following.

We shall examine more in detail in later sections the reasoning which leads to Eq. (2.7). We only note here that the argument made here is legitimate only in *classical* mechanics so that a certain revision is required to apply it to quantum-mechanical cases. The revised form is rather easily anticipated from the results of the previous paper. We shall discuss this in the next section.

Before doing that, we shall briefly describe here the classical derivation of (2.2) from (2.1) for the convenience of later reference. We multiply the both sides of Eq. (2.1) by α_l' and average them with the probability distribution density $W(\alpha_1', \cdots \alpha_n')$, which is the stationary probability for the realization of the values $(\alpha_1', \cdots \alpha_n')$ in the aged system. The left-hand side becomes evidently the correlation functions which appear in Eq. (2.2). The right-hand side is now transformed as

$$
\begin{aligned}
&\sum_m G_{jm}\Delta t\int\cdot\cdot\int \alpha_l'\left\{\frac{\partial}{\partial\alpha_m'}S(\alpha_1'\cdots\alpha_n')\right\}\cdot W(\alpha_1'\cdots\alpha_n')d\alpha_1'\cdots d\alpha_n' \\
&= k\sum_m G_{jm}\Delta t\int\cdot\cdot\int \alpha_l'\frac{\partial}{\partial\alpha_m'}W(\alpha_1'\cdots\alpha_n')d\alpha_1'\cdots d\alpha_n' \\
&= -kG_{jl}\Delta t
\end{aligned}
$$

which coincides with the right-hand side of Eq. (2.2). We made here use of the assumption

$$W(\alpha_1'\cdots\alpha_n') = C\exp\left\{\frac{1}{k}S(\alpha_1\cdots\alpha_n')\right\} \qquad (2.9)$$

where C is the normalization constant.

§ 3. Application of Onsager's Assumption

For quantum-mechanical systems, it is not always possible to define a simultaneous distribution of the observed values of α_1, α_2, $\cdots$ and α_n. Or more specifically, we may not be able to prepare a statistical ensemble like that defined classically by (2.9). This is so because such variable are not necessarily commutable with each other or with the Hamiltonian itself. It is true that they are nearly commutable if they are really macroscopic quantities. But still caution is requir-

---

* If the condition (2.6) is not fulfilled, Eqs. (2.3) and (2.7) must be corrected by the additional term.

$$-\frac{1}{k}\langle \dot\alpha_j\alpha_l\rangle = \frac{1}{k}\langle \alpha_j\dot\alpha_l\rangle\,.$$

** The infinite integral here is rather the Cesaro limit as one sees at once from the last form of Eq. (2.3). The Cesaro limit may be replaced by the Abel limit,

$$\lim_{\varepsilon\to+0}\int e^{-\varepsilon t}\langle \dot\alpha_j(t)\dot\alpha_l(0)\rangle\, dt\,.$$

We omitted here more rigorous mathematical statement because physicists are rather accustomed to use improper integrals which are summarable in some way or another.

ed for the effect which may enter as a consequence of non-commutability.

Considering this circumstance, we propose here to interprete Onsager's assumption in a little less stringent way than what Eq. (2.1) literally implies. Namely, we now regard $\overline{\alpha_j(t+\Delta t|\alpha')}$ as the expectation of the variable α_j at the time $t+\Delta t$ for a statistical ensemble for which the variables $(\alpha_1, \cdots \alpha_n)$ have the expectation values $(\alpha_1', \cdots, \alpha_n')$ at the time t. This ensemble is represented by the statistical operator $\rho(t+\Delta t|\alpha')$ which, by definition, has the properties,

$$\mathrm{Tr}\,\rho(t+0|\alpha')\alpha_j=\alpha_j' , \tag{3.1}$$

$$\mathrm{Tr}\,\rho(t+\Delta t|\alpha')\alpha_j=\overline{\alpha_j(t+\Delta t|\alpha')} . \tag{3.2}$$

According to our new interpretation, Eq. (2.1) is now read as

$$\mathrm{Tr}\,\rho(t+\Delta t|\alpha')\alpha_j-\alpha_j'=\sum_k G_{jk}\frac{\partial S}{\partial \alpha_k'}\Delta t . \tag{3.3}$$

Now the question is what will be this density matrix $\rho(t+0|\alpha')$. This is the most subtle point of the whole argument. It seems to us that the most natural answer for the form of $\rho(t+0|\alpha')$ is

$$\rho(t+\Delta t(\alpha')=\exp[\beta(\Omega-\mathscr{H})-\beta\sum A_j\alpha_j] , \tag{3.4}$$

which is a sort of canonical distribution. Here Ω is a free energy and A_j's $(j=1, 2, \cdots, n)$ are scalar quantities which are defined by the conditions (3.1) and correspond to the forces associated with the coordinates α_j's. The density operator (3.4) is the solution of maximization problem of the entropy

$$S=-k\,\mathrm{Tr}\,\rho\log\rho , \tag{3.5}$$

with the supplementary conditions (3.2) and other well known conditions. The parameters A_j's enter here as the undetermined multipliers. We see at once that

$$\beta\frac{\partial\Omega}{\partial A_j}=\bar{\alpha}_j-\alpha_j' , \tag{3.6}$$

$$S=-k\beta\Omega+k\beta\mathscr{H}+\sum_j kA_j\bar{\alpha}_j , \tag{3.7}$$

where $\mathscr{H}$ and $\bar{\alpha}_j$ are the everage values for the ensemble represented by (3.4), and

$$\frac{\partial S}{\partial \alpha_j'}=k\beta A_j . \tag{3.8}$$

Therefore Eq. (3.3) now becomes

$$\mathrm{Tr}\exp[\beta(\Omega-\mathscr{H})-\beta\sum_l A_l\alpha_l]\{\alpha_j(\Delta t)-\alpha_j(0)\}$$
$$=k\beta\sum_l G_{jl}A_l\Delta t . \tag{3.9}$$

where $\alpha_j(\tau)$ means the Heisenberg representation of the variable α_j. Namely they are defined by

$$\dot{\alpha}_j(\tau)=\frac{1}{i\hbar}[\alpha_j(\tau), \mathscr{H}] ,$$
$$\alpha_j(\tau)=\exp(i\mathscr{H}\tau/\hbar)\,d\exp(-i\mathscr{H}\tau/\hbar) .$$
(3.10

We now assume the linear dissipative systems, so that the deviation from the equilibrium is small. This means that the forces A_j's are really small. Thus we expand the left-hand side of Eq. (3.9) and leave only the linear term. Using the formula

$$\exp[-\beta\mathscr{H}-\beta\sum_l A_l\alpha_l]$$
$$=\exp(-\beta\mathscr{H})$$
$$-\int_0^\beta \exp(-\beta\mathscr{H})\sum_l A_l\,\alpha_l(-i\hbar\lambda)d\lambda+o(A) ,$$
(3.11

we obtain at once

$$\overline{\alpha_j(t+\Delta t|\alpha')}=\langle\alpha_j\rangle$$
$$-\sum A_l\int_0^\beta\langle\alpha_l(-i\hbar\lambda)\alpha_j(\Delta t)\rangle d\lambda$$
$$+o(A) .$$
(3.12

where $\langle\ \rangle$ means the average over the equilibrium distribution $\exp\beta(\Omega^0-\mathscr{H})$ so that $\langle\alpha_j\rangle$ is the equilibrium value of α_j. Eq. (3.12) reduces, in particular for $\Delta t=0$, to

$$\overline{\alpha_j(t|\alpha')}\equiv\alpha_j'$$
$$=\langle\alpha_j\rangle-\sum_l A_l\int_0^\beta\langle\alpha_l(-i\hbar\lambda)\alpha_j\rangle d\lambda$$
$$+o(A) ,$$
(3.13

which is the condition to determine the forces A in terms of the deviation $\alpha_j'-\langle\alpha_j\rangle$ from the equilibrium. The set of Eq. (3.13) is equivalent to Eq. (3.6).

Inserting Eq. (3.11) into (3.9) we get easil

$$\frac{1}{\beta}\int_0^\beta\langle\alpha_l(i\hbar\lambda)\{\alpha_j(\Delta t)-\alpha_j(0)\}\rangle d\lambda$$
$$=-kG_{jl}\Delta t ,$$
(3.14

which corresponds to Eq. (2.2), as we see from the fact that the left-hand side of Eq. (3.14) becomes the correlation function appearing in Eq. (2.2) in the classical lim $\hbar\to 0$.

Like Eq. (2.4) for the classical correlatio function, we evidently have the relation

$$\frac{d^2}{d\tau^2}\int_0^\beta\langle\alpha_l(-i\hbar\lambda)\alpha_j\rangle d\lambda$$
$$=-\int_0^\beta\langle\dot{\alpha}_l(-i\hbar\lambda)\dot{\alpha}_j(\tau)\rangle d\lambda .$$
(3.1

Thus, if the condition

$$\int_0^\beta \langle \dot{\alpha}_l(-i\hbar\lambda)\alpha_j \rangle \, d\lambda$$
$$= -\int_0^\beta \langle \alpha_l(-i\hbar\lambda)\dot{\alpha}_j \rangle \, d\lambda = 0 \,, \tag{3.16}$$

is satisfied, Eq. (3.14) can be transformed into

$$G_{jl} = \frac{1}{k\beta}\int_0^{\Delta t}\left(1-\frac{\tau}{\Delta t}\right)d\tau$$
$$\times \int_0^\beta \langle \dot{\alpha}_l(-i\hbar\lambda)\dot{\alpha}_j(\tau) \rangle \, d\lambda \,. \tag{3.17}$$

just in the same way as we did in Eq. (2.3). If, furthermore, the characteristic time of decay of the integrand of (3.17) is small enough compared with that which corresponds to (2.8), Eq. (3.17) gives

$$G_{jl} = \frac{1}{k\beta}\int_0^\infty d\tau \int_0^\beta \langle \dot{\alpha}_l(-i\hbar\lambda)\dot{\alpha}_j(\tau) \rangle \, d\lambda \,. \tag{3.18}$$

as the wanted expression for the kinetic coefficient G_{jl}. The infinite integral may be regarded as the Cesaro limit or the Abel limit. We note finally that the condition (3.16) is satisfied if

$$\frac{1}{i\hbar}\langle [\alpha_l, \alpha_j] \rangle = 0 \,, \tag{3.19}$$

that is, if α_l and α_j are commutable on the average. The equivalence of (3.19) to (3.16) is seen from the identity, Eq. (3.7) of I, i.e.,

$$[\exp(-\beta\mathscr{H}), A]$$
$$= i\hbar \int_0^\beta \exp(-\beta\mathscr{H})\dot{A}(-i\hbar\lambda)\, d\lambda \,. \tag{3.20}$$

Therefore we have

$$\int_0^\beta \langle \dot{\alpha}_l(-i\hbar\lambda)\alpha_j \rangle \, d\lambda$$
$$= (i\hbar)^{-1}\,\mathrm{Tr}\,[\exp\beta(\Omega^0-\mathscr{H}), \alpha_l]\alpha_j$$
$$= (i\hbar)^{-1}\,\mathrm{Tr}\exp\beta(\Omega^0-\mathscr{H})[\alpha_l, \alpha_j] \,.$$

It should be remembered that the expression (3.18) becomes rigorous only when the choice of infinitely large Δt is proved to be possible for the particular choice of the variables α. Otherwise, it remains only a certain approximation.

This should be particularly emphasized, because we see in literatures certain confusion about this point.[6)][7)] Some of formulae of the type (2.17) or (3.18) given in literatures are by no means rigorous since the above-mentioned choice of $\Delta t \to \infty$ is simply impossible. These approximate formulae, though we should not underestimate their usefulness, must be discriminated from such rigorous formulae as we are concerned with in the present work.

For instance, the expression of conductivity, $S_{\mu\nu}{}^{(1)}$ in Eq. (4.6) of the present paper, which was derived in the preceding paper I, is rigorous. We may write this as

$$\sigma = \int_0^\infty \int_0^\beta \langle J_x J_x(t+i\hbar\lambda) \rangle \, d\lambda dt = \frac{ne}{m^*}\tau \,, \tag{3.21}$$

where we defined the effective mass m^* by

$$\frac{ne}{m^*} = \int_0^\beta \langle J_x J_x(i\hbar\lambda) \rangle \, d\lambda \,,$$

(see Eq. (8.12), I) and the average relaxation time τ by

$$\tau = \int_0^\infty \phi(t)dt \,, \tag{3.22}$$

with

$$\phi(t) = \int_0^\beta \langle J_x J_x(t+i\hbar\lambda) \rangle \, d\lambda \Big/ \int_0^\beta \langle J_x J_x(i\hbar\lambda) \rangle \, d\lambda \,. \tag{3.23}$$

Now an approximation for this relaxation time is given by

$$\frac{1}{\tau} \sim -\int_0^{\tau_c} \ddot{\phi}(t)dt$$
$$= \int_0^{\tau_c} dt \int_0^\beta \langle \dot{J}_x \dot{J}_x(t+i\hbar\lambda) \rangle \Big/ \int_0^\beta \langle J_x J_x(i\hbar\lambda) \rangle d\lambda \,, \tag{3.24}$$

which may be used as good approximation under certain restricted conditions. Namely it may be used when the function $\phi(t)$ behaves like $\exp(-t/\tau)$, or in other words, when the spectrum of relaxation time of $\phi(t)$ is nearly degenerate. It is easy to show that Eq. (3.24) gives the Grüneisen formula when applied to electrons scattered by phonons.[8)] One of the present authors proved many years ago that the Grüneisen formula is derived from the Bloch equation by calculating the average of the relaxation frequencies and equating this to the reciprocal of the average relaxation time τ in Eq. (3.21).[9)]

We may see the approximation (3.24) roughly by applying the same transformation technique as used for Eqs. (2.3) and (3.17) to the function $\phi(t)$, that is,

$$\phi(t) = 1 + \int_0^t (t-\tau)\ddot{\phi}(\tau)d\tau \sim 1 + t\int_0^{\tau_c}\ddot{\phi}(\tau)d\tau \,. \tag{3.25}$$

The last form may be used for t which is much longer than the characteristic time τ_d

of $\ddot{\phi}(\tau)$ and shorter than the relaxation time τ of $\phi(t)$ provided that such a choice of t is possible.* For such t, $\phi(t)$ is decreasing as $1-t/\tau$, τ being that defined by Eq. (3.24). Note that here the assumption is introduced for the existence of a plateau value of the integral, i.e.,

$$\int_0^t \ddot{\phi}(\tau)d\tau \sim \int_0^{\tau_c} \ddot{\phi}(\tau)\,d\tau\ ,$$

for $\tau_d \ll t \ll \tau$.

It is essential in the expression (3.24) to stop the integration at a finite upper limit, because we ought to have

$$\int_0^\infty dt \int_0^\beta \langle\, \dot{j}_x \dot{j}_x(t+i\hbar\lambda)\,\rangle\, d\lambda = 0\ , \tag{3.26}$$

if the integral (3.21) does exist.

It should be also noticed that the Kirkwood formula[6]

$$\zeta = m/\tau = \beta \int_0^{\tau_c} \langle\, \dot{P}_x \dot{P}_x(t)\, dt\ , \tag{3.27}$$

for the friction constant ζ of a Brownian particle is simply a special case of Eq. (3.24).

Thus the Kirkwood formula (3.27) and the similar formula (3.24) rely upon rather restricted assumptions about the nature of $\phi(t)$, which can by no means be proved to be generally valid. On the other hand, Eq. (3.21) itself is rigorous and fundamental as was proved in I and also in § 4 of the present paper. We should discriminate between these two classes of expressions for kinetic coefficients.

§ 4. Electron Transport Phenomena

Let us now consider, as an illuminating example of the argument made in the preceding sections, the electronic transport phenomena in metals or semi-conductors. According to the phenomenological theory,[10] the electric current density $\boldsymbol{j}$ and the heat flow density $\boldsymbol{q}$ are linear functions of the gradients of the electrochemical potential

$$\mu = \zeta - e\varphi\ , \tag{4.1}$$

of the electrons and the gradient of temperature. The charge of electron is taken here as $-e$. Namely we have

$$\boldsymbol{j} = \mathfrak{S}^{(1)}\left(\boldsymbol{E} + \frac{T}{e}\nabla\xi\right) + \mathfrak{S}^{(2)}\frac{1}{T}\nabla T$$

$$\boldsymbol{q} = -\mathfrak{S}^{(3)}\left(\boldsymbol{E} + \frac{1}{e}\nabla\xi\right) - \mathfrak{S}^{(4)}\frac{1}{T}\nabla T\ , \tag{4.2}$$

where $\boldsymbol{E}$ is the electric field and ξ is defined by

$$\xi = \zeta / T\ . \tag{4.3}$$

Eq. (4.2) can be written as

$$\boldsymbol{E} = \rho\,\boldsymbol{j} - \frac{1}{e}\mathfrak{S}\nabla T - \frac{1}{e}\nabla\zeta$$

$$\boldsymbol{q} = \pi\boldsymbol{j} - \kappa\nabla T - \frac{1}{e}\zeta\boldsymbol{j}\ , \tag{4.4}$$

where the constants are

$$\begin{aligned} \rho &= \mathfrak{S}^{(1)-1} = \sigma^{-1}\ , \\ \mathfrak{S} &= (e\rho\mathfrak{S}^{(2)} - \zeta)\,/\,T\ , \\ \pi &= -\mathfrak{S}^{(3)}\rho - \zeta/T\ . \\ \kappa &= (\mathfrak{S}^{(4)} - \mathfrak{S}^{(3)}\rho\mathfrak{S}^{(2)})\,/\,T\ . \end{aligned} \tag{4.5}$$

Here ρ is the electric resistance, κ the heat conductivity, $-\mathfrak{S}/e$ the absolute thermoelectric power per unit temperature difference, and π is the Peltier constant. All of $\mathfrak{S}^{(r)}$ $(r=1,\cdots 4)$ and other coefficients are tensors of the second rank. Our problem is now to find exact expressions for these coefficients in Eqs. (4.2) or (4.4).

The answer is easily anticipated, because we know already the exact expression of $\mathfrak{S}^{(1)}$, that is the conductivity tensor. Thus we want to show that the equations,

$$\begin{aligned} S^{(1)}_{\mu\nu} &= \int_0^\infty \int_0^\beta \langle\, j_\nu j_\mu(t+i\hbar\lambda)\,\rangle\, d\lambda dt \\ S^{(2)}_{\mu\nu} &= \int_0^\infty \int_0^\beta \langle\, q_\nu j_\mu(t+i\hbar\lambda)\,\rangle\, d\lambda dt \\ S^{(3)}_{\mu\nu} &= \int_0^\infty \int_0^\beta \langle\, j_\nu q_\mu(t+i\hbar\lambda)\,\rangle\, d\lambda dt \\ S^{(4)}_{\mu\nu} &= \int_0^\infty \int_0^\beta \langle q_\nu q_\mu(t+i\hbar\lambda)\,\rangle\, d\lambda dt\ , \end{aligned} \tag{4.6}$$

hold as rigorous expressions for these kinetic coefficients. Expressions similar to Eqs. (4.6) have been given indepently by Mori[7]. His formulae, however, differ from (4.6) in the upper limit of the time integral which he put as finite. This reflects the difference of the ways of reasoning. We shall show that it can be extended to infinity and that Eqs. (4.6) are rigorous in their nature. We follow the line of reasoning described in the foregoing sections in order to arrive at these results.

---

* Physically, the function $\ddot{\phi}(t)$ corresponds to the time correlation of forces acting on the electrons. The characteristic time τ_d of this will be the duration time of collision if the electrons are scattered by phonons or other perturbers only with rare chances and short duration of collision.

It is most convenient to consider the electron number density $n(\boldsymbol{r})$ and the energy density $\mathcal{E}(\boldsymbol{r})$. We regard an electron gas system with the volume V as an isolated system and define the total entropy as the sum of entropy density under the assumption of local equilibrium. The local entropy density is a function of $n(\boldsymbol{r})$ and $\mathcal{E}(\boldsymbol{r})$. Thus the entropy S can be expanded in terms of fluctuations $\Delta n(\boldsymbol{r})$ and $\Delta\mathcal{E}(\boldsymbol{r})$ of $n(\boldsymbol{r})$ and $\mathcal{E}(\boldsymbol{r})$ as

$$\begin{aligned} S &= \int s(\boldsymbol{r})d\boldsymbol{r} \\ &= \int\left[s_0 + \frac{\partial s}{\partial\mathcal{E}}\Delta\mathcal{E} + \frac{\partial s}{\partial n}\Delta n + \frac{1}{2}\left\{\frac{\partial^2 s}{\partial\mathcal{E}^2}(\Delta\mathcal{E})^2 + 2\frac{\partial^2 s}{\partial\mathcal{E}\partial n}(\Delta\mathcal{E}\,\Delta n) + \frac{\partial^2 s}{\partial n^2}(\Delta n)^2\right\}\right]d\boldsymbol{r} + \cdots \\ &= S_0 + \frac{1}{2}\left(\frac{\partial}{\partial\mathcal{E}}\frac{1}{T}\right)\int(\Delta\mathcal{E})^2 d\boldsymbol{r} + \left(\frac{\partial}{\partial n}\frac{1}{T}\right)\int\Delta\mathcal{E}\Delta n d\boldsymbol{r} - \frac{1}{2}\left(\frac{\partial}{\partial n}\right)\int(\Delta n)^2 d\boldsymbol{r} + \cdots, \end{aligned} \tag{4.7}$$

where S_0 is the equilibrium entropy of whole system so that the linear terms in $\Delta\mathcal{E}$ and Δn must vanish. We made in Eq. (4.7) use of the relations,

$$\frac{\partial s}{\partial\mathcal{E}} = \frac{1}{T}, \quad \text{and} \quad \frac{\partial s}{\partial n} = -\frac{\zeta}{T}.$$

Now the fluctuations $\Delta\mathcal{E}(\boldsymbol{r})$ and $\Delta n(\boldsymbol{r})$ are developed in the Fourier components. Eq. (4.7) is rewritten as

$$S = S - \frac{1}{2}\frac{1}{T^2}\left(\frac{\partial T}{\partial\mathcal{E}}\right)_n V\sum_{\boldsymbol{k}}\mathcal{E}_{\boldsymbol{k}}\mathcal{E}_{-\boldsymbol{k}} - \frac{1}{T^2}\left(\frac{\partial T}{\partial n}\right)_{\mathcal{E}} V\sum_{\boldsymbol{k}}\mathcal{E}_{\boldsymbol{k}}n_{-\boldsymbol{k}} - \frac{1}{2}\left(\frac{\partial\xi}{\partial n}\right)_{\mathcal{E}} V\sum_{\boldsymbol{k}} n_{\boldsymbol{k}}n_{-\boldsymbol{k}} + \cdots, \tag{4.8}$$

where $n_{\boldsymbol{k}}$ and $\mathcal{E}_{\boldsymbol{k}}$ are the Fourier components of $n(\boldsymbol{r})$ and $\mathcal{E}(\boldsymbol{r})$ respectively.

The general thermodynamics of irreversible processes here asserts that the flows $\dot{\mathcal{E}}_{\boldsymbol{k}}$ and $\dot{n}_{\boldsymbol{k}}$, when they are present as macroscopic observables and hence their fluctuation is neglected, are linearly related to the driving forces, $\partial S/\partial n_{\boldsymbol{k}}$ and $\partial S/\partial\mathcal{E}_{\boldsymbol{k}}$. Namely the phenomenological equations are

$$\dot{n}_{\boldsymbol{k}} = \sum_{\boldsymbol{k}'} G^{(1)}_{\boldsymbol{k}\boldsymbol{k}'}\frac{\partial S}{\partial n_{\boldsymbol{k}'}} + \sum_{\boldsymbol{k}'} G^{(2)}_{\boldsymbol{k}\boldsymbol{k}'}\frac{\partial S}{\partial\mathcal{E}_{\boldsymbol{k}'}}, \qquad \dot{\mathcal{E}}_{\boldsymbol{k}} = \sum_{\boldsymbol{k}'} G^{(3)}_{\boldsymbol{k}\boldsymbol{k}'}\frac{\partial S}{\partial n_{\boldsymbol{k}'}} + \sum_{\boldsymbol{k}'} G^{(4)}_{\boldsymbol{k}\boldsymbol{k}'}\frac{\partial S}{\partial\mathcal{E}_{\boldsymbol{k}'}}, \tag{4.9}$$

which, with the aid of Eq. (4.8), are written as

$$\begin{aligned} \dot{n}_{\boldsymbol{k}} &= -V\sum_{\boldsymbol{k}'} G^{(1)}_{\boldsymbol{k}\boldsymbol{k}'}\left\{\left(\frac{\partial\xi}{\partial n}\right)_{\mathcal{E}} n_{-\boldsymbol{k}'} + \frac{1}{T^2}\left(\frac{\partial T}{\partial n}\right)_{\mathcal{E}}\mathcal{E}_{-\boldsymbol{k}'}\right\} \\ &\quad - V\sum_{\boldsymbol{k}'} G^{(2)}_{\boldsymbol{k}\boldsymbol{k}'}\left\{\frac{1}{T^2}\left(\frac{\partial T}{\partial n}\right)_{\mathcal{E}} n_{-\boldsymbol{k}'} + \frac{1}{T^2}\left(\frac{\partial T}{\partial\mathcal{E}}\right)_n\mathcal{E}_{-\boldsymbol{k}'}\right\} \\ \dot{\mathcal{E}}_{\boldsymbol{k}} &= -V\sum_{\boldsymbol{k}'} G^{(3)}_{\boldsymbol{k}\boldsymbol{k}'}\left\{\left(\frac{\partial\xi}{\partial n}\right)_{\mathcal{E}} n_{-\boldsymbol{k}'} + \frac{1}{T^2}\left(\frac{\partial T}{\partial n}\right)_{\mathcal{E}}\mathcal{E}_{-\boldsymbol{k}'}\right\} \\ &\quad - V\sum_{\boldsymbol{k}'} G^{(4)}_{\boldsymbol{k}\boldsymbol{k}'}\left\{\frac{1}{T^2}\left(\frac{\partial T}{\partial n}\right)_{\mathcal{E}} n_{-\boldsymbol{k}'} + \frac{1}{T^2}\left(\frac{\partial T}{\partial\mathcal{E}}\right)_n\mathcal{E}_{-\boldsymbol{k}'}\right\}. \end{aligned} \tag{4.10}$$

The flows $\boldsymbol{j}(\boldsymbol{r})$ and $\boldsymbol{q}(\boldsymbol{r})$ are related to the densities $n(\boldsymbol{r})$ and $\mathcal{E}(\boldsymbol{r})$ by the phenomenological equations,*

---

* These equations leave an ambiguity for the current components which are derived from the antisymmetric part of the tensors $\mathfrak{S}^{(r)}$, which vanish automatically in the divergence.[1] Thus the following argument is, strictly speaking, incompetent as the proof of the antisymmetric parts of Eqs. (4.6). This point will be considered in a forthcoming paper.

$$\dot{n}(\boldsymbol{r})=\frac{1}{e}\operatorname{div}\boldsymbol{j}(\boldsymbol{r}) ,$$

$$\dot{\varepsilon}(\boldsymbol{r})=-\operatorname{div}\boldsymbol{q}(\boldsymbol{r}) , \tag{4.11}$$

so that we have

$$\dot{n}_{\boldsymbol{k}}=\frac{1}{e}i(\boldsymbol{k}\boldsymbol{j}_{k}) ,$$

$$\dot{\varepsilon}_{\boldsymbol{k}}=-i(\boldsymbol{k}\boldsymbol{q}_{k}) , \tag{4.12}$$

where $\boldsymbol{j}_{\boldsymbol{k}}$ and $\boldsymbol{q}_{\boldsymbol{k}}$ are the Fourier components of the flow densities. Inserting the Fourier components of Eq. (4.2) into Eq. (4.12) and making use of the equations,

$$\nabla T=\frac{\partial T}{\partial\varepsilon}\nabla\varepsilon+\frac{\partial T}{\partial n}\nabla n ,$$

$$\nabla\xi=\frac{\partial\xi}{\partial\varepsilon}\nabla\varepsilon+\frac{\partial\xi}{\partial n}\nabla n .$$

we obtain

$$e\dot{n}_{\boldsymbol{k}}=-\left(\frac{T}{e}\frac{\partial\xi}{\partial\varepsilon}\boldsymbol{k}\mathfrak{S}^{(1)}\boldsymbol{k}+\frac{1}{T}\frac{\partial T}{\partial\varepsilon}\boldsymbol{k}\mathfrak{S}^{(2)}\boldsymbol{k}\right)\varepsilon_{\boldsymbol{k}}$$
$$-\left(\frac{T}{e}\frac{\partial\xi}{\partial n}\boldsymbol{k}\mathfrak{S}^{(1)}\boldsymbol{k}+\frac{1}{T}\frac{\partial T}{\partial n}\boldsymbol{k}\mathfrak{S}^{(2)}\boldsymbol{k}\right)n_{\boldsymbol{k}}$$

$$\dot{\varepsilon}_{\boldsymbol{k}}=-\left(\frac{T}{e}\frac{\partial\xi}{\partial\varepsilon}\boldsymbol{k}\mathfrak{S}^{(3)}\boldsymbol{k}+\frac{1}{T}\frac{\partial T}{\partial\varepsilon}\boldsymbol{k}\mathfrak{S}^{(4)}\boldsymbol{k}\right)\varepsilon_{\boldsymbol{k}}$$
$$-\left(\frac{T}{e}\frac{\partial\xi}{\partial n}\boldsymbol{k}\mathfrak{S}^{(3)}\boldsymbol{k}+\frac{1}{T}\frac{\partial T}{\partial n}\boldsymbol{k}\mathfrak{S}^{(4)}\boldsymbol{k}\right)n_{\boldsymbol{k}} . \tag{4.13}$$

Comparing Eq. (4.10) with Eq. (4.13) we find that

$$eVG^{(r)}_{\boldsymbol{k},-\boldsymbol{k}}=\frac{T}{e}\boldsymbol{k}\mathfrak{S}^{(r)}\boldsymbol{k} , \qquad r=1,\cdots 4, \tag{4.14}$$

and that

$$G^{(r)}_{\boldsymbol{k},\boldsymbol{k}'}=0 , \qquad \text{if} \quad \boldsymbol{k}+\boldsymbol{k}'\neq 0 .$$

These relations must hold in order that the "thermodynamic" relations, (4.9), are consistent with the phenomenological equations (4.2).

Now we are in position to apply our logics of previous section to obtain rigorous expressions for $G^{(r)}_{k,-k}$. Eq. (3.14) is now read as

$$\frac{1}{\beta}\int_0^\beta\langle n_{-\boldsymbol{k}}(t-i\hbar\lambda)\{n_{\boldsymbol{k}}(t+\Delta t)-n_{\boldsymbol{k}}(t)\}\rangle d\lambda=-kG^{(1)}_{\boldsymbol{k},-\boldsymbol{k}}\Delta t ,$$
$$\frac{1}{\beta}\int_0^\beta\langle \varepsilon_{-\boldsymbol{k}}(t-i\hbar\lambda)\{n_{\boldsymbol{k}}(t+\Delta t)-n_{\boldsymbol{k}}(t)\}\rangle d\lambda=-kG^{(2)}_{\boldsymbol{k},-\boldsymbol{k}}\Delta t .$$
$$\frac{1}{\beta}\int_0^\beta\langle n_{-\boldsymbol{k}}(t-i\hbar\lambda)\{n_{\boldsymbol{k}}(t+\Delta t)-\varepsilon_{\boldsymbol{k}}(t)\}\rangle d\lambda=-kG^{(3)}_{\boldsymbol{k},-\boldsymbol{k}}\Delta t ,$$
$$\frac{1}{\beta}\int_0^\beta\langle \varepsilon^{-}{}_{\boldsymbol{k}}(t-i\hbar\lambda)\{\varepsilon_{\boldsymbol{k}}(t+\Delta t)-\varepsilon_{\boldsymbol{k}}(t)\}\rangle d\lambda=-kG^{(4)}_{\boldsymbol{k},-\boldsymbol{k}}\Delta t . \tag{4.15}$$

By the remark made at the end of § 3, it is evident that we have

$$\int_0^\beta\langle n_{-\boldsymbol{k}}(t-i\hbar\lambda)\,\dot{n}_{\boldsymbol{k}}(t)\rangle d\lambda=0 ,$$

and

$$\int_0^\beta\langle \varepsilon_{-\boldsymbol{k}}(t-i\hbar\lambda)\,\dot{\varepsilon}_{\boldsymbol{k}}(t)\rangle d\lambda=0 .$$

Corresponding expressions containing $n_{\boldsymbol{k}}$ and $\varepsilon_{\boldsymbol{k}}$ are also zero, because we have by virtue of Eq. (3.20)

$$\int_0^\beta\langle \dot{n}_{-\boldsymbol{k}}(t-i\hbar\lambda)\,\varepsilon_{\boldsymbol{k}}(t)\rangle d\lambda=\frac{1}{i\hbar}\langle[n_{-\boldsymbol{k}},\varepsilon_{\boldsymbol{k}}]\rangle=-i(\boldsymbol{k}\boldsymbol{j})/e .$$

The last expression is obtained by explicit calculation of the commutator $[n_{-\boldsymbol{k}},\varepsilon_{\boldsymbol{k}}]$ in terms of quantized wave functions. The average of current in equilibrium is equal to zero, so that we may put

$$\int_0^\beta\langle n_{-\boldsymbol{k}}(t-i\hbar\lambda)\,\dot{\varepsilon}_{\boldsymbol{k}}(t)\rangle d\lambda=\int_0^\beta\langle \varepsilon_{-\boldsymbol{k}}(t-i\hbar\lambda)\dot{n}_{\boldsymbol{k}}(t)\rangle d\lambda=0 .$$

Therefore we can safely rewrite Eqs. (4.14) in the form of Eq. (3.17).

Furthermore, Eq. (4.14) shows that the decay of the functions on the left-hand sides of Eq. (4.15) becomes infinitely slow if the wave number k approaches to zero. Speaking in classical language, the time of the decay of the fluctuation of n and $\mathcal{E}$ becomes infinitely slow as the wave length of the spacial fluctuation becomes infinitely large. This is physically evident. This provides a sound basis for the transformation of Eq. (4.15) into the expressions of the type Eq. (3.18) in the limit of $k\to 0$. Thus we arrive at the equations

$$\begin{aligned}
\lim_{k\to 0} G^{(1)}_{k,-k} &= \lim \frac{1}{k}\int_0^\infty\int_0^\beta \langle \dot{n}_{-k}(-i\hbar\lambda)\, \dot{n}_k(t)\rangle\, d\lambda dt\,, \\
\lim_{k\to 0} G^{(2)}_{k,-k} &= \lim \frac{1}{k}\int_0^\infty\int_0^\beta \langle \dot{\mathcal{E}}_{-k}(-i\hbar\lambda)\, \dot{n}_k(t)\rangle\, d\lambda dt\,, \\
\lim_{k\to 0} G^{(3)}_{k,-k} &= \lim \frac{1}{k}\int_0^\infty\int_0^\beta \langle \dot{n}_{-k}(-i\hbar\lambda)\, \dot{\mathcal{E}}_k(t)\rangle\, d\lambda dt\,, \\
\lim_{k\to 0} G^{(4)}_{k,-k} &= \lim \frac{1}{k}\int_0^\infty\int_0^\beta \langle \dot{\mathcal{E}}_{-k}(-i\hbar\lambda)\, \dot{\mathcal{E}}_k(t)\rangle\, d\lambda dt\,. \qquad (4.16)
\end{aligned}$$

Now Eq. (4.12) is used to rewrite the expressions on the right-hand sides of these equations and the resulting expressions are compared with Eq. (4.14). Thus we find that Eq. (4.6) are obtained rigorously from Onsager's assumption.

Growth of Oxide Whiskers on Metals at High Temperature

By Riitsu TAKAGI

Government Mechanical Laboratory, Sumiyoshi-cho, Suginami-ku, Tokyo

(Received July 15, 1957)

Growths of α-Fe_2O_3 whiskers formed on pure iron in oxygen at 400~850°C were studied by electron microscopy and diffraction using specimens cut off successively from a uniformly oxidized wire which was heated consecutively to avoid ill effect of contamination condensed during electron-microscopic observation. Whisker grows at the tip by surface diffusion of molecules from base to tip. Axial growth at a fixed temperature is approximately given by: $l=kt^{0.3}$, where k, a constant, depends on temperature and has a maximum at 700~750°C. Initial diameter corresponds to that which gives the minimum strength necessary to keep whisker shape at the growth temperature. A whisker has an axis parallel to $<110>_{\text{hex}}$, becoming thereafter blade-shaped crystal parallel to (001). Further growth at the tip of a blade-shaped crystal occurs at those sites which are in a plane parallel to (001), and similar growth happens on a fracture surface of a mechanically truncated crystal, too.

§ 1. Introduction

Whisker growths on the surfaces of metals and alloys oxidized at high temperatures were recently investigated by Pfefferkorn[1], Takagi[2], Cowley[3], Morita et al.[4], and Arnold & Koonce[5] either with electron microscope or with a combination of electron microscope and diffraction. Since current theory of oxidation of metals fails to account for this phenomenon,[6] interest was aroused in their growth behavior. Pfefferkorn pointed out, after tracing the growth of a particular needle crystal on phosphor bronze or iron by alternating oxidation and observation, that these oxide needles grow at their tips by means of surface diffusion of constituent elements, and Cowley, from the fine structure of electron diffraction spots obtained with his high resolution apparatus, explained the characteristic structure of CuO needles as resulting from growth about one or more screw dislocations.

In course of our electron-microscopic study of the growth of oxide whiskers subsequent to the previous paper[2] we found it impossible to trace the natural growth of a particular oxide whisker by observing successively in electron microscope. Then we devised a new method of observation avoiding the ill effect of electron irradiation on the natural growth. The object of the present paper is primarily to report the results obtained by this method and in consequence to clarify the growth processes of oxide whiskers in conformity with the facts known from the conventiona oxidation theory.

§ 2. Experimental

It was found that most conspicuous whiske growths are seen in Fe_2O_3 on iron and steel CuO on copper and phosphor bronze, and Zn on zinc and brass. Among them iron appear to be the most suitable material for stud since wide temperature range of the whiske formation exists below melting point of th metal and the structure of the oxide, $\alpha-Fe_2O_3$ is fairly simple (rhombohedral)*. Hence w used pure iron in most of the experiments Results with other metals are reported fo supplementary purposes in this paper.

Iron specimens were of purest materia available. Electrolytic iron was subjected t re-electrolysis, and then vacuum cast an drawn into a wire of diameter 0.3 mm, whic was kindly given by Mr. T. Nagashima o Electrotechnical Laboratory. Drawn wire wa annealed for three hours at 850°C in flowin purified hydrogen. Surfaces of the iro specimen were electropolished in a fresh bat of a mixture of H_3PO_4 90% and H_2SO_4 10 using lead cathode.

Heating furnace was a tube of 2 cm i diameter and 30 cm in length wound externa ly with nichrome wire. Both ends of th tube were equipped with rubber stoppers through which tank oxygen dried by passage over $CaCl_2$ and P_2O_5 was kept flowing at an approximate rate of 50 cc/min. Temperature of the specimen was measured by a thermocouple placed in the furnace and automatically kept constant.

---

*) For convenience hexagonal indices will b used throughout.

For successive observation of growth behavior of a particular whisker, a piece of wire, 3 mm in length, was passed across an electron microscope specimen supporter and was placed in the central region of the furnace, to be repeatedly heated and observed (*Method A*). But since this direct way of studying growth with an electron microscope was regrettably found to be accompanied with a serious drawback, following alternative method (*Method B*) was adopted. An iron wire, 5 cm in length, was fixed to a frame of nichrome wire at one end and uniformly oxidized in the furnace. A 3 mm-long piece was cut off from the free end of the wire, and it was observed under electron microscope. The rest of the wire was preserved and used for further oxidation. The process of heating the remaining wire and cutting off a specimen can be continued again and again as long as the wire is long enough for the next specimen. Accelerating voltage of electron beam was 50 kV for microscopy and 70 kV for diffraction.

§ 3 Results

(1) *Factors influencing upon the formation and growth of whiskers*

Atmosphere: Densities of whiskers formed in air were compared with those formed i oxygen. Whiskers on iron and copper had large preference for oxygen, while those o zinc and brass showed little difference between the two atmospheres.

Temperature: Temperature ranges withi

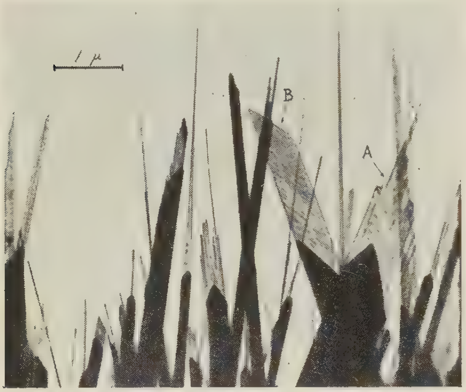

Photo. 5. Further growth at 500°C in 100 min. on the tips of Fe_2O_3 crystals formed at 750°C in 100 min.

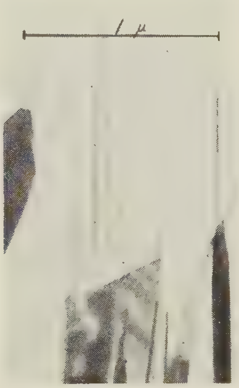

Photo. 6. Further growth at 500 C in 20 min. on a fracture surface of an Fe_2O_3 crystal formed at 725°C in 40 min.

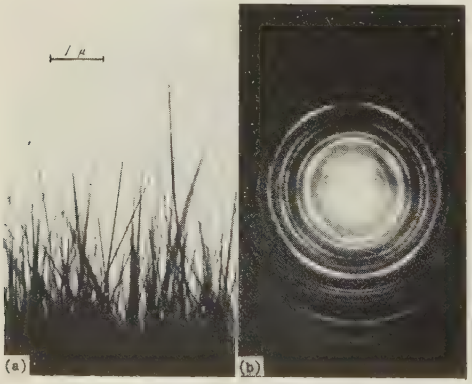

Photo. 7. (a) Fe_2O_3 whiskers formed at 650°C in 30 min. (b) Electron diffraction pattern of the specimen shown in (a).

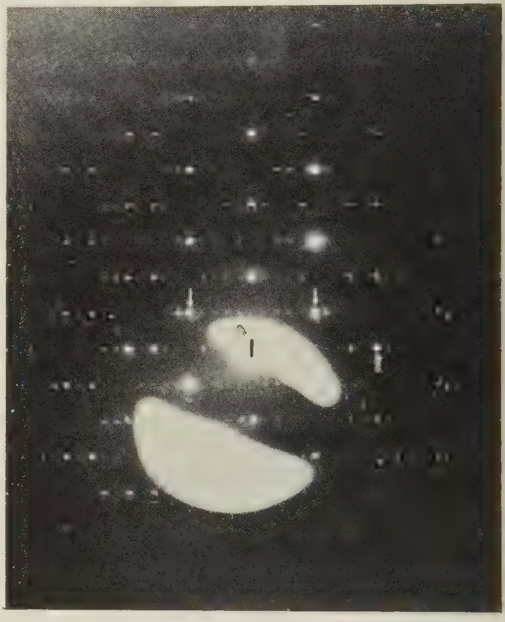

Photo. 8. Electron diffraction pattern of an Fe_2O_3 crystal formed at 700°C in 2 h. The beam coming through a hole in Al film is parallel to [001]. Bright area of Al around the hole due to partial transmission of electron beam casts diffuse shadow of specimen, which facilitates correct movement of the specimen. Probable position of the crystal in the shadow image is indicated by a black line. Note a line of 9 anomalous spots between 2 normal spots indicated, e.g., by 2 downward white arrows. $(\bar{3}30)$ spot is indicated by an upward arrow.

Photo. 9. Coagulation after electron irradiation of Fe_2O_3 crystals formed at 700°C in 20 min.

which whiskers readily grow in oxygen are listed in the following table.

Iron and steel	400∼850°C
Copper and phosphor bronze	400∼550 〃
Zinc and brass	300∼850 〃

Surface impurity: A remarkable property found for iron is that the attachment of a small amount of moist substance or slight touch of finger tip on electropolished clean surface accelerates the whisker formation.*

Electron irradiation: Most of the whiskers once observed by an elcetron microscope do not grow in a natural way, but those located just outside the field of view and received little electron beam irradiation grow quite naturally on heating them afterwards in an oxygen atmosphere. The cessation of normal axial growth due to electron beam irradiation is presumably caused by the condensation of carbonaceous contamination on the growth site at the tip of the whiskers.

(2) *Successive observation of whisker growth*

(*a*) *Growth of a particular whisker* (*Method A*). Photo. 1 shows the growth of ZnO on oxidized zinc. Whiskers in Photo. 1 grow either at the tip or at the branchings directed to an angle of 60 or 120° from the tip direction. Photo. 2 shows CuO on copper, where some grow normally (such as A) while the other stop their axial growth and increase in thickness. Thinner oxide is seen growing at the tip of a thickened crystal (B).

(*b*) *Growth of whiskers in general* (*Method B*). When one and the same heating temperature was used throughout several repeated cycles of heating the wire, cutting off a specimen and observation, whiskers did not show any sign of discontinuity in thickness along their length. General trend of axial growth was estimated from experiments specially designed for that purpose: A series of several electron micrographs were successively taken for different heating times at a fixed heating temperature. The length of the longest whisker on each electron micrograph was measured and plotted against time as shown in Fig. 1. Though scattering of individual points is considerable as might have been expected from the method of measurement, yet a straight line may be drawn for each heating temperature, which is approximated by the general equation

$$l = kt^{0\cdot 3},$$

where l is whisker length, t is time and k is a constant. k depends on temperature and attains a maximum value at 700∼750°C.

Whisker thickness increased as the heating temperature was raised, and Fig. 2 shows the minimum thickness estimated from an electron micrograph of the specimen heated for one minute at each temperature. By utilizing the fact that whisker thickness changes remarkably with heating temperature, next experiments were carried out: An iron specimen was heated in the first place at 500°C and, after ascertaining the growth of thin whiskers, then heated at 700°C. It was found electron-microscopically that thin whiskers which had grown at 500°C disappeared entirely on heating at 700°C, so that solely thicker whiskers grown at 700°C remained there. On the contrary, when thicker whiskers

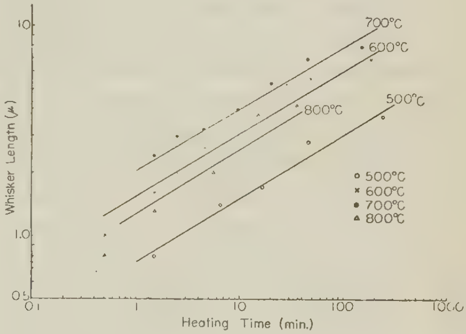

Fig. 1.

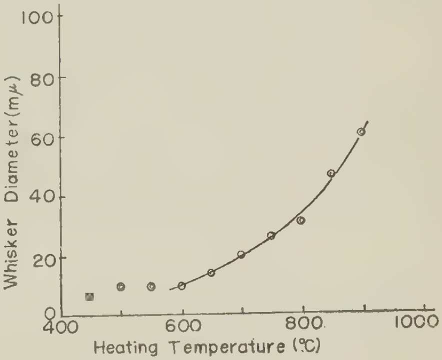

Fig. 2. Minimum whisker thickness. Lowest three points are near the resolution limit and uncertain.

---

*) In this connection Fricke et al.7) obtained Fe_2O_3 needles by heating γ-FeOOH in air.

grown in the first place at 700°C (*P*) were heated subsequently at 500°C, thin whiskers (*S*) grew at the tips of the original thicker whiskers (Photo. 3 (a) and (b)). When this specimen was again heated at 700°C, *S* parts disappeared completely while *P* parts remained with increase in thickness (Photo. 3 (c)). When these remaining *P* parts were heated again at 500°C, thin whiskers grew at the tips of the thicker whiskers as before (Photo. 3 (d)). The usually observed behavior of initial formation of *S* whisker is shown in Photo. 4, where many tiny crystallites are formed apparently independently of each other on the advancing edge of a blade-shaped crystal, gradually growing together into a sheet of single crystal as they grow further afterwards (Photo. 5, A). There are, however, some crystals showing exceptionally parallel growth, such as B in Photo. 5. It seems in both cases that the place where a plane passing through the axis of the crystal and parallel to the flat blade surfaces meets the advancing edge of the original crystal has a particular ability of providing *S* crystal with growth site on subsequent heating. When a *P* crystal broken mechanically by rolling the oxidized straight wire between two parallel glass plates kept at an appropriate distance was further heated at 500°C, *S* crystal grew on the fracture surface likewise (Photo. 6), but nothing grew from the broken pieces.

(3) *Electron diffraction observation*

Photo. 7 (b) is an electron diffraction pattern of densely grown α-Fe_2O_3 whiskers, and from the fiber diagram which is the direction of whisker axis can be determined to be <110>. The direction is in accord with the result of Miyake[8)], who reported the fiber orientation of Fe_2O_3 on oxidized iron surface though he did not refer it to whisker growth. Single crystal electron diffraction pattern of a relatively thick crystal produced at 600∼800°C could be obtained by a three-stage electron microscope or, more accurately, by placing an aluminum film with a hole of about 5 $\mu\phi$ in front of the specimen and sliding the specimen relative to the hole in search of an appropriately oriented crystal (e.g. Photo. 8). Photo. 8 shows a pattern of α-Fe_2O_3 always obtained when the crystal is placed so that its (001) plane, which is parallel to flat blad surfaces, is normal to the electron beam where lines of anomalous spots correspondin to a period equal to ten times the spacing o ($3\bar{3}0$) plane can be seen besides normal cross grating spots. This period, 14.35 Å, is equa to a length of a line of five contiguous oxyge ions when α-Fe_2O_3 is supposed to consist o close-packed oxygen ions. In cases of Zr and CuO, no regular row of anomalous spot was observed except for extraordinary elongation of diffraction spots reported earlier[2)3)

§ 4. **Discussion**

(1) *Tip growth*

From the results described in § **3** (2) (*b*), i is known that *S* crystal grows at the tip o *P* crystal. In principle we cannot find an discontinuity in the growth mechanism at th boundary of *P* and *S*, which are two differen parts of the same crystal, and the apparen departure at the boundary from the norma growth is merely the discontinuous change i thickness due to abrupt fall of temperatur in the course of its growth. Hence it ma be generally concluded that crystals grow a their tips even when there are no observabl thickness changes. Results of Photos. 1 an 2 also indicate the tip growth. But there th situation is rather complicated and it is supposed as follows: Contaminant film attache on to the growth site at the tip during observation stops the axial growth temporarily and thickening takes place; the latter seem less sensitive to contamination. When th contaminant film on the tip is broken, axia growth is resumed by a thin whisker.

(2) *Material supply*

There are three possible processes of supplying materials for growing oxide whiskers (i) Evaporation followed by condensation, (ii surface diffusion, and (iii) internal diffusion The process (i) occurs partly in ZnO in th form of zinc atoms since the vapor pressur of zinc at the temperature employed is, as i well-known, quite high. Actually ZnO whiskers were often observed growing at place separated from zinc or zinc oxide. But Fe_2O or CuO whiskers were found only on the respective metal or oxide showing that th process (i) is negligible. Internal diffusion o material which usually requires higher activa ion energy than surface diffusion is unlikely n Fe_2O_3 whiskers from the following considerations: It is known that during oxidation of iron the main diffusing component in the outermost Fe_2O_3 layer is the oxygen advancing from O_2/Fe_2O_3 interface through Fe_2O_3 phase up to Fe_2O_3/Fe_3O_4 interface, in the form of oxygen ion vacancy and electron diffusing in the reverse direction.[9] If Fe_2O_3 whiskers grow by this mechanism, they should grow at their base instead of the experimentally found tip of whiskers. Since other possible processes of internal diffusion are less likely to occur, it may be supposed that Fe_2O_3 whiskers, and most of the other oxide whiskers, too, grow by surface diffusion, provided that evaporation is negligible. High mobility of the constituent elements on the surface is indicated by the meniscus-shaped accumulation of material at the contact places of two crystals described by Pfefferkorn,[1] and also by the spherical coagulation generated when Fe_2O_3 whiskers are irradiated with intense electron beam giving rise to extraordinary local thinnings without still any bending or breaking of whiskers (Photo. 9).

Oxidation theory of iron described in the preceding paragraph further reveals that Fe_2O_3 whiskers are not buried in the bulk oxide from the base during later oxidation, since Fe_2O_3 layer grows in thickness at the inner interface Fe_2O_3/Fe_3O_4, so that the measured whisker length in Fig. 1 contains no error arising from this source.

If we assume that (i) the increase in whisker length is effected solely through surface diffusion of oxide molecules adsorbed on the whisker surface from base to tip, (ii) the evaporation of adsorbed molecules is negligible, and (iii) surface concentration of adsorbed molecules at a given time during growth varies simply linearly along the length of the whisker just like the variation of concentration of ratedetermining diffusing component along the oxide layer thickness in conventional parabolic oxidation theory, axial growth would be expressed by $l \propto t^{0 \cdot 5}$ under constant temperature and radius. The difference in rate from the experimentally found axial growth may be ascribed to the radial growth which is actually observed.

(3) *Thickness of whiskers*

It was known that thickness of whiskers increases as they are heated at heigher temperatures and for longer periods. But we may suppose that thickness of whiskers, at the outset of their growth at a given temperature i.e. nearly the value given by Fig. 2, corresponds to the diameter of a crystal having the minimum shear strength necessary to maintain the whisker shape against surface tension force at that temperature. The observation shown in Photo. 3 can then be explained in such a way that the crystal parts grown at 500°C collapsed at 700°C because they do not have enough strength at 700°C. Actually, however, whiskers formed grow slowly in radial direction, particularly in directions parallel to (001) plane which is approximately close-packed with larger oxygen ions, so that most of the observed whiskers have considerably larger thickness than that indicated in Fig. 2.

(4) *Formation and growth of whiskers*

We have treated the problem by surface diffusion of oxide molecules without regard to how oxidation really takes place. In this respect present problem is not much diffferent from the growth of needle crystals on tungsten when oxidized tungsten is heated in vacuum where evaporation and condensation of tungsten oxide takes place considerably besides surface diffusion.[10] In order to make it clearer that an oxide whisker forms in some way and grows by surface diffusion it would be convenient to assume the existence of perpetual step at the tip provided by screw dislocation with Burgers vector parallel to the whisker axis as Cowley[3] has done. These dislocations will be produced, for instance, by slip in Fe_2O_3 crystals due to stress generated during the formation and growth of Fe_2O_3 layer. Once a screw dislocation is produced in an appropriate direction of a crystallite, molecules adsorbed on the surface migrate toward the step until the crystal grows to a diameter large enough for preserving whisker shape. After that the axial growth commences.

It seems from the observations shown in Photos. 4 and 5 that on the advancing edge of a whisker numerous growth steps are distributed in a line on a plane parallel to the basal plane. Though we cannot satisfactorily explain how such a particular plane occurs in a crystal, it appears that the particular plane persists within crystal even after the crystal has fully grown, as shown by Photo.

6. We cannot find the relation, if any, between the assumed dislocations and the periodic imperfections found by electron diffraction as shown in Photo. 8.

In conclusion, the author wishes to express his sincere thanks to Professor Ryozi Uyeda for suggestion of this problem and continude interest during this work. He is also indebted to Dr. T. Kawada for encouragement and advice.

Theory of Viscoelasticity of Amorphous Polymers

II. A Note on the Time-Temperature Reducibility of the Relaxation and Retardation Spectra

By Osamu NAKADA*

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received June 8, 1957)

Equivalence of temperature change and shift of log-time scale is usually assumed empirically in obtaining a master curve of relaxation and retardation spectra in polymers.

In this paper the molecular theoretical basis of this assumption—which we call here the *time-temperature reducibility*—is elucidated by an examination of the generalized diffusion equation in the configuration space of a polymer chain.

Several criterions for the reducibility are deduced as the results of the analysis which in fact give a gurantee to the reducibility in the case of simple intra-chain relaxation phenomena in amorphous polymers. Critical examinations of some other cases are also made.

§ 1. Introduction

Extensive progress has been made recently in measuring the dynamic response of various polymers in very wide frequency ranges, and thus characteristic features of relaxation phenomena in polymers have been elucidated progressively.[1]

But in actual experiments a single run of the measurement can cover in most cases only a limited range of frequency which is usually rather narrow compared with the required range of the relaxation spectrum. Thus, in order to get a complete relaxation spectrum, we usually make resort to the assumption that a change of temperature in observations of relaxation phenomena is equivalent to a proper shift of log-time scale.[2),3),4),5)] This assumption enables us to constract a " master

---

curve" of the relaxation spectrum at reference temperature by shifting and joining successively a number of segmental curves obtained at different temperatures. We will call here the assumption mentioned in the above the *time-temperature reducibility.* (Cf. § 2) It is indeed probable that such an assumption of reducibility is satisfied at least approximately in a narrow range of frequency and temperature in the case of amorphous polymers. But it is open to question whether it really holds over the whole range of the spectrum required. Unless the physical ground for validity of the assumption is clarified, we may not be able to rely upon the obtained master curves of the relaxation spectrum based on the assumption.

In the following we will try to elucidate the applicability of the time-temperature reducibility from a molecular theoretical aspect.*)

§ 2. The Time-Temperature Reducibility of the Relaxation Spectrum and of the Retardation Spectrum

The dynamic elastic modulus, e.g. the shear modulus G, can be expressed in general as a function of angular frequency ω and of temperature T in the following integral form:

$$G(\omega, T)=G_0(T)+\int_{-\infty}^{\infty}\frac{i\omega\tau H(\tau, T)}{1+i\omega\tau}d(\ln\tau)\,, \quad (1)$$

where G_e is the static elastic modulus (i.e. the modulus for zero frequency). The function $H(\tau, T)$ in the integrand is called the distribution function of relaxation times or simply the relaxation spectrum, and the variable τ is called the relaxation time.

According to Ferry et. al.,[4] the effect of temperature on the relaxation spectrum is assumed as follows: First, the integral of the equation (1) is interpreted as representing an ensemble of rubberlike elastic elements. Then $H(\tau, T)$ should be proportional to the absolute temperature. Next, *all* relaxation times τ's of elastic elements are assumed to be multiplied by the *same* shift factor a_T when temperature is changed from T_0 to T. Thus

$$H(\tau, T)=(T/T_0)H(\tau/a_T, T_0) \quad (2)$$

$$a_T=1 \quad \text{at} \quad T=T_0\,. \quad (3)$$

Since, however, the introduction of the factor T/T_0 in the above equation in analogy with the rubber elasticity is without ground,**) we here define the *time-temperature reducibility* of the relaxation spectrum by the following equations:

$$H(\tau, T)=\beta_G(T)H(\alpha_G(T)\tau, T_0) \quad (4)$$

$$\alpha_G(T_0)=1\,. \quad (5)$$

These relations are visualized in Fig. 1. If the relaxation spectrum $H(\tau, T)$ is time-temperature reducible, the log (modulus) *vs.* log (frequency) curves at diverse temperatures can be superposed on a single master curve at a reduced temperature by proper shifts of original curves along both axes.

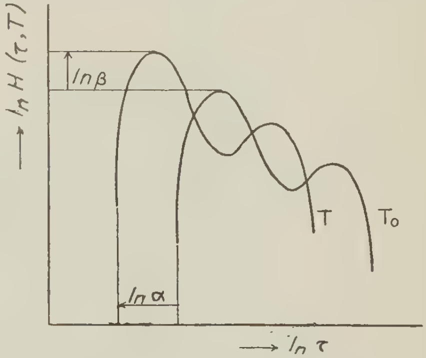

Fig. 1. A schematic diagram of a time-temperature reducible relaxation spectrum $H(\tau, T)$.

The reducibility of the retardation spectrum is defined in a similar manner. The dynamic elastic compliance $J(\omega, T)$ is expressed with the aid of the retardation spectrum $L(\tau, T)$ as

$$J(\omega, T)=J_\infty(T)+\int_{-\infty}^{\infty}\frac{L(\tau, T)}{1+i\omega\tau}d(\ln\tau)\,, \quad (6)$$

where J_∞ denotes the compliance in high frequency limit.

---

* Recently Onogi and Ui made an experimental confirmation of the time-temperature reducibility for polyvinylidene-vinyl chloride fibre and PVC-DMT gel. (S. Onogi, K. Ui: J. Colloid Sci. **11** (1956) 214.) On the other hand, Okano discussed the reducibility from the viewpoint of thermodynamics of irreversible processes. (K. Okano: Reps. of the Sci. Res. Inst. **32** (1956) 197.)

** The relaxation spectrum $H(\tau, T)$ may be considered to be a product of the factor $\lambda(\tau, T)$ representing the intensity of each relaxing element and the factor $\mu(\tau, T)$ representing the density of elements in the range $d\tau$. Indeed the intensity factor λ will be proportional to the absolute temperature if we assume the each element to be rubberlike, but the density factor μ will also depend on temperature in general. Accordingly the relaxation spectrum H will not necessarily be proportional to the absolute temperature. (Cf. reference (6))

Then we define the reducibility of the retardation spectrum $L(\tau, T)$ by

$$L(\tau, T)=\beta_J(T)L(\alpha_J(T)\tau, T_0) \tag{7}$$

$$\alpha_J(T_0)=1\ . \tag{8}$$

Real and imaginary parts of $G(\omega, T)$ and $J(\omega, T)$, $H(\tau, T)$, and $L(\tau, T)$ are not independent of each other, and if one of them is given in the whole range of the variable, others are derivable from it.[7] Hence the relations (3) and (4) can not be independent of relations (7) and (8). According to Gross,[7] the relaxation spectrum $H(\tau)$ is derived from the retardation spectrum $L(\tau)$ by the following formula.

$$H(\tau)=\frac{L(\tau)}{[\Omega(\tau)]^2+[\pi L(\tau)]^2} \tag{9}$$

$$\Omega(\tau)=J_\infty(\tau)+\Omega'(\tau) \tag{10}$$

$$\Omega'(\tau)=\int_{-\infty}^{\infty}\frac{\tau L(u)}{\tau-u}d(\ln u)\ . \tag{11}$$

Substituting Eq. (7) into Eqs. (10) and (11), we get

$$\left.\begin{aligned}\Omega(\tau, T)&=J_\infty(T)+\beta_J\int_{-\infty}^{\infty}\frac{\alpha_J\tau L(u, T_0)}{\alpha_J\tau-u}d(\ln u)\\&=\frac{J_\infty(T)}{J_\infty(T_0)}J_\infty(T_0)+\beta_J\Omega'(\alpha_J\tau, T_0)\ .\end{aligned}\right\} \tag{12}$$

Thus we see from Eqs. (9), (10) and (12) that the reducibility of the retardation spectrum leads to the reducibility of relaxation spectrum if J_∞ is negligible compared to Ω', or if

$$\frac{J_\infty(T)}{J_\infty(T_0)}=\beta_J=(T)\ . \tag{13}$$

Also it will be seen from Eq. (9) that when the reducibilities of the relaxation and retardation spectra are compatible with each other shift factors of the two spectra are related by

$$\beta_G=1/\beta_J(T)\ , \qquad \alpha_G=\alpha_J\ . \tag{14}$$

Since the fulfilment of the condition (13) will be rather fortuitous, it will be necessary that J_∞ is negligible compared to Ω' in order that the reducibility of the retardation spectrum is compatible with the reducibility of the relaxation spectrum. These circumstances will be discussed again in the later section (§5). In the following we confine our discussion in the reducibility of the retardation spectrum in the convenience of a molecular theoretical treatment.

§3. Phenomenological Meaning of the Reducibility

When the step function-like stress,

$$\sigma=\begin{cases}0\ , & t<0\\ \sigma_0\ , & t\geq 0\end{cases} \qquad (15$$

is applied to the system which has the dynami compliance given by Eq. (6), the retarde strain γ of the system increases with tim according to the following equation as it i well known in the phenomenological theor of linear viscoelasticity,[8]

$$\gamma(t)=\left\{\int_{-\infty}^{\infty}L_J(\tau)[1-e^{-t/\tau}]d(\ln\tau)\right\}\sigma\ . \qquad (1$$

The function in the curly bracket in the abov equation is usually called the creep function

The retarded response of the system unde δ-functionlike stress,

$$\sigma=\sigma_0\delta(t) \qquad (17$$

is given by the derivative of Eq. (16)[8]

$$\gamma'(t)=\left\{\int_{-\infty}^{\infty}\frac{1}{\tau}L_J(\tau)e^{-t/\tau}d(\ln\tau)\right\}\sigma\ . \qquad (18$$

Substituting Eqs. (7) and (8) into Eqs. (16 and (18), we get

$$\gamma(t, T)=\beta_J(T)\gamma(t^*, T_0) \qquad (19$$

$$\gamma'(t, T)=\alpha_J(T)\beta_J(T)\gamma'(t^*, T_0) \qquad (20$$

$$t^*=\alpha_J(T)t\ . \qquad (21$$

These equations derived in the above wil tell us the phenomenological meaning of the time-temperature reducibility: *When the system has the reducible retardation spectrum the intensity and the rate of the response o the system against external excitations are in creased or reduced along with a temperature change only by constant factors which depen only on temperature.*

§4. The Molecular Theoretical Basis of the Reducibility

Now we proceed to the molecular theoretica consideration of the physical meaning of the time-temperature reducibility.

The system is assumed to be uniform and to be composed of microscopic structural units such as molecules, chain segments, network chains etc. We denote by q's a set of generalized coordinates which are sufficient to describe the configuration of the structural unit, and we define a probability distribution function $f(q)$ in such a way that the probability of a unit to be in small range dq equals $f(q)dq$. We consider a *simple* macroscopic quantity X which is determined directly by the distri-

ution function of the unit $f(q)$ in the follow-
ng way:

$$X(t, T)-X_0(T)=c\int x(q)[f(q, t, T)-f_0(q, T)]dq \tag{22}$$

Iere suffix zero means a value in equiliblium;
(q) is a microscopic physical quantity cor-
esponding to X; and c is a constant deter-
ined by an arrangement of units.

In amorphous cross-linked polymers we may
hoose as a structural unit a network chain
etween adjacent cross-links, and simple
acroscopic quantities such as polarization,
hear strain, refractive index, etc. are deter-
ined directly by corresponding microscopic
uantities, i.e. dipole moment, end-to-end
istance, polarizability, etc. of a network chain.

Now in order that the strain γ satisfies the
ondition of the reducibility, Eq. (19) to Eq.
0), it is sufficient, so far as we assume γ to
e one of simple macro-quantities, that the
eviation of the distribution function $f-f_0$ is
educible in a similar way:

$$f_1\equiv f-f_0=\lambda(T)g(q, t^*, T_0) \tag{23}$$

$$t^*=\alpha(T)t \tag{24}$$

he relations, (23) and (24), are obviously more
eneral than the relations (19) or (20) and (21),
volving that all first order deviations of
mple macro-quantities should be reducible in
me and temperature. So we will distinguish
e two by calling the latter the *macroscopic*
educibility and the formers the *microscopic*
educibility. We have, however, some evi-
ences in relaxation in polymers for that the
acroscopic reducibility is originated from the
icroscopic reducibility, as we shall see later.
f. § 5) So hereafter we will seek for con-
itions of the microscopic reducibility.

Under the influence of thermal agitation
ructural units of the system are changing
eir configrations incessantly in the medium.*)
herefore, the change of configurations of
nits with time is described properly by a
eneralized diffusion equation which can be
t up in the following way.9)

The distribution function of the structural
nit satisfies the equation of continuity in the
onfiguration space,

$$\operatorname{div} j+\frac{\partial f}{\partial t}=0 \tag{25}$$

Here j is the flux of the probability density in the configuration space, which is composed of four components:

$$j=j_d+j_m+j_i+j_e \tag{26}$$

where

$$j_d=-\left(\frac{kT}{\zeta}\right)\operatorname{grad} f \tag{27}$$

$$j_m=v_m f \tag{28}$$

$$j_i=\frac{1}{\zeta}F_i f \tag{29}$$

$$j_e=\frac{1}{\zeta}F_e f, \qquad \text{or} \quad =v_e f \tag{30}$$

Here ζ means the friction tensor of the structural unit in the medium, v_m the flow velocity of the medium, v_e the additional excitation flow of the medium. F_i the force exerted internally to the unit, and F_e the additional excitation force exerted externally to the unit. The first component j_d means the diffusion flow which obeys Fick's law. The second component j_m is the flow along with a motion given to the medium. The third component j_i is due to forces exerted internally to the unit. The last component j_e means the flow corresponding to a small excitation exerted to the unit by an external force F_e or by an additional excitation flow v_e of the medium. Substituting Eqs. (26), (27), (28), (29) and (30) into Eq. (25) we get the required generalized diffusion equation for the structural unit in the configuration space $\{q\}$.

Now assuming that the external excitation is given by the force F_e which is sufficiently small we expand the distribution function f in power series of the external excitation force F_e:

$$f=f_0+f_1+O(F_e^2) \tag{31}$$

Substituting Eq. (31) into Eq. (25) and taking account of Eqs. (26) to (30), we get the following equation for f_1.

$$\mathrm{L}f_1+\frac{\partial f_1}{\partial t}=-\operatorname{div}\left(\frac{1}{\zeta}F_e f_0\right) \tag{32}$$

Here L is an operator given by

$$\mathrm{L}=\mathrm{L}_d+\mathrm{L}_m+\mathrm{L}_i \tag{33}$$

$$\mathrm{L}_d=-kT\operatorname{div}\frac{1}{\zeta}\operatorname{grad}\cdot \tag{34}$$

$$\mathrm{L}_m=\operatorname{div} v_m\cdot \tag{35}$$

---

* By the term “medium” we mean any homo-
enious surrounding of a representative unit, which
ay be either a foreign solvent or structural units
emselves.

$$\mathrm{L}_i = \mathrm{div}\ \frac{1}{\zeta} F_i . \qquad (36)$$

In the case where the excitation is given by a flow of the medium v_e we need only replace F_e/ζ in the above equations by v_e.

For the purpose to examine the reducibility, it is sufficient to consider the response of the system to the δ-function-like excitation. If δ-function-like force F_e is applied to the system, the right hand side of Eq. (32) becomes also a δ-function, so that

$$\mathrm{L} f_1 + \frac{\partial f_1}{\partial t} = 0 , \qquad \text{for} \quad t > 0 . \qquad (37)$$

First we assume that the microscopic reducibility, i.e. Eqs. (23) and (24), holds for the system. Then substituting Eq. (23) into Eq. (37), we get

$$\mathrm{L} g + \frac{\partial g}{\partial t} = 0 , \qquad t > 0 . \qquad (38)$$

Or, taking account of Eq. (24),

$$\frac{1}{\alpha(T)} \mathrm{L} g = -\frac{\partial g}{\partial t^*} , \qquad t^* > 0 . \qquad (39)$$

Since the function g defined in Eq. (23) is assumed not to depend on temperature explicitly, the righthand side of the Eq. (39) does not depend on the variable T, so that $\mathrm{L}/\alpha(T)$ on the lefthand side of the equation also should not contain T explicitly. The reverse statement of the above deduction can be easily verified by retracing the equations. Therefore the necessary and sufficient condition for the microscopic reducibility is that the operator L in Eq. (32) can be writen in a form,

$$\mathrm{L} = \alpha(T) \mathrm{L}_0 \qquad (40)$$

where α is a shift factor which is function of T, and L_0 is an operator which does not depend on T explicitly.

According to Eqs. (34) to (36), three components of the operator L, i.e. L_d, L_m and L_i depend on temperature in mutually different manners so that Eq. (40) does not hold generally when more than one components coexist in L. Therefore the microscopic reducibility should hold only in the following three cases:

$$\left.\begin{array}{lll} \text{i)} & \mathrm{L}_d \neq 0, & \mathrm{L}_m = \mathrm{L}_i = 0 \\ \text{ii)} & \mathrm{L}_m \neq 0, & \mathrm{L}_d = \mathrm{L}_i = 0 \\ \text{iii)} & \mathrm{L}_i \neq 0, & \mathrm{L}_d = \mathrm{L}_m = 0 \end{array}\right\} \qquad (41)$$

Moreover, in order that the operator L can be expressed in the form of Eq. (40) the friction tensor ζ should be written in a form,

$$\zeta = \phi(T) \zeta_0 \qquad (42)$$

where $\phi(T)$ is a scalar constant which depen only on temperature and ζ_0 is a tensor whic is independent of temperature. Then the shi factor $\alpha(T)$ in each of three cases in Eq. (4 is given by

$$\alpha(T) = \left\{ \begin{array}{ll} kT/\phi(T) & \text{for case (i)} \\ 1 & \text{for case (ii)} \\ 1/\phi(T) & \text{for case (iii) .} \end{array} \right\} \qquad (4$$

As far as we consider the irreversible flo phenomena along the line developed here, can not eliminate essentially the diffusion fl operator L_d, so that cases (ii) and (iii) can be realized in a strict sense. It might however, realized in an approximate sense a low temperature where $\mathrm{L}_d \ll \mathrm{L}_m$ or $\mathrm{L}_d \ll$

An approximate reducbibility also holds we see in the following, when the activati energy of the elementary process of the fl is sufficiently large. If we assume convenient the Andrade's equation for the temperatu dependence of the friction constant i.e., if assume

$$\phi(T) = A T^n e^{E/kT} , \qquad (4$$

relative changes of magnitudes of the operato L_d and L_i can be written as

$$\left.\begin{array}{l} \dfrac{\Delta|\mathrm{L}_d|}{|\mathrm{L}_d|} = \left(\dfrac{\partial}{\partial T} \ln |\mathrm{L}_d| \right) \Delta T \\ \qquad = \{(E/kT) - (n-1)\}(\Delta T/T) \end{array}\right\} \qquad (4$$

$$\frac{\Delta|\mathrm{L}_i|}{|\mathrm{L}_i|} = \{(E/kT) - n\}(\Delta T/T) . \qquad ($$

Accordingly in the case where

iv) $E/kT \gg n$ and 1, $\mathrm{L}_m = 0$,

the temperature dependence of L_d and L_i comes almost the same, and

$$\Delta \mathrm{L} = \Delta \alpha(T) \mathrm{L}_0 , \qquad ($$

so that the microscopic reducibility holds proximately at least in a comparatively sm temperature range.

§ 5 Applications to the Relaxation of Po mers

Now we will apply the criterions for reducibility of the retardation spectrum tained in the above to actual cases. T reducibility of the spectrum has been us most effectively in determing master curv of shear relaxation spectra of amorphous po mers such as polyisobutylene in very w frequency ranges.[10] It is well establis both experimentally and theoretically that shear relaxation spectrum of linear amorphous polymers consist mainly of two parts, the *wedge* type part in a shorter relaxation time range and the *box* type part in a longer relaxation time region.[11] The former originates from the configurational relaxation of each of chains between junctions,[6][12][13] and the latter implies the relaxation of the junctions themselves which are either temporary entanglements or secondary bonds between chains.[14][15][16] So cross-linked polymers such as vulcanized rubber which are considered to have permanent chemical junctions between chains naturally lack the box type spectrum. Besides the wedge and box spectra, there often appears a third relaxation region in high frequency in certain polymers, which can be usually attributed to rotation of a side group. In the following, we will examine these cases in turn, as well as some other cases.

a) The wedge type spectrum. As a structural unit in this case we may choose a network chain between adjacent junction points. The macroscopic shear strain may be assumed to be proportional to the microscopic strain of network chains. It should be emphasized that in homogeneous amorphous polymers the internal energy does not change effectively with the change of configurations of the network chain, so that the internal force F_i acting on a chain can be neglected. Hence the operator L is made up of only one component L_d when the flow of the medium is zero. While, the friction tensor ζ can be expressed in the form of Eq. (42), since the underlying elementary processes are the same for all internal freedoms of the chain. Thus it turns out that the configurational relaxation of a chain in amorphous polymers belongs to the case (i) in Eq. (41) which together with Eq. (42), guarantees the microscopic reducibility and hence also the macroscopic reducibility of the retardation spectrum.

In order to prove the reducibility of the relaxation spectrum, it is necessary to verify the compatibility of the reducibility of the relaxation and retardation spectra. Ω' in Eq. (11) can be evaluated approximately as follows:

$$\Omega'(\tau)=\int_{-\infty}^{\infty}\frac{\tau \mathrm{L}(u)}{\tau-u}d(\ln u)\simeq\int_{-\infty}^{\ln\tau}\mathrm{L}(u)d(\ln u)$$

$$-\int_{\ln\tau}^{\infty}\frac{\tau}{u}\mathrm{L}(u)d(\ln u)\simeq\int_{-\infty}^{\ln\tau}\mathrm{L}(u)d(\ln u) \quad (48)$$

Now from Eq. (6) it is seen, with the use of Alfrey's approximation, that

$$J(\omega, T)\simeq J_\infty+\int_{-\infty}^{\ln(1/\omega)}\mathrm{L}(\tau, T)d(\ln\tau) \quad (49)$$

With the aid of Eq. (49), Eq. (48) can be rewritten as

$$\Omega'(\tau)\simeq J(1/\tau)-J_\infty \quad (50)$$

Except when τ takes a value quite near to the shortest retardation time, the relation

$$J(1/\tau)-J_\infty\gg J_\infty \quad (51)$$

holds experimentally in amorphous polymers. From Eqs. (50), (51) and (11), it is seen that

$$\Omega'\gg J_\infty \quad (52)$$

for the major range of the retardation spectrum, which is sufficient for the compatibility of the two spectra.

Thus we see the time temperature reducibility is valid in the wedge type relaxation spectrum.

b) The box type spectrum. In this case we can not take a network chain as the structural unit, because here the relaxation phenomena concern with the inter-chain interaction of rater complex nature—i.e. breaking and reforming of entanglements or secondary bonds among chains. Nevertheless, we should be able to formulate the problem, at least in principle, in the formalism developed in § 3, if we can choose a proper structural unit. The structural unit in this case should contain an internal freedom concerning to breaking and reformation of junctions.

Thus, in the problem of the box type spectrum, the essential point consists in the nature of temporary junctions. If they would be of energetic nature, e.g. caused by hydrogen bonds or dipolar interactions, the intervention of a L_i term should prevent the time-temperature reducibility to hold in rigorous sense. If, on the countary, junctions would be merely caused by entanglements without any special interaction between chains, the reducibility should hold favourably in the box type region as well as in the wedge type region. Non-polar linear polymer like polyisobutylene $[CH_2CH(CH_3)_n$ may belong to the favourable case.

c) The side group relaxation. The typical example of the relaxation of this type is found in polymethylmethacrylate $[CH_2C(CH_3)COOCH_3]_n$, in which rotational relaxation of $(COOCH_3)$

group is considered to take place in a higher frequency.[14]

Apart from the wedge and box spectra, the spectrum of the side group relaxation alone may be time-temperature reducible. But it can not be reducible simultaneously with the wedge and box spectra, since the relaxing unit in this case will be quite different from that of the wedge-box parts. In terms of our formulation it should imply the inadequacy of Eq. (42); instead, the friction tensor will be written in a form

$$\zeta=\left[\begin{array}{c|c} \phi_1(T)\zeta_1 & 0 \\ 0 & \phi_2(T)\zeta_2 \end{array}\right] \qquad (53)$$

where $\phi_1\zeta_1$ corresponds to the side group relaxation, and $\phi_2\zeta_2$ to the wedge-box relaxation. Thus the two relaxation processes may be treated seperately, so far as the two relaxation region does not overlap. In these cases the shift factor α depends not only on temperature as usually assumed, but also on the kind of relaxing unit, and may be better expressed by

$$\alpha_k(T)\,, \qquad k=1, 2, \cdots, \qquad (54)$$

where k denotes the kind of the relaxing unit.

d) Relaxations in crystalline polymers. Crystalline polymers are usually imagined to be made up of fine crystalline phases embedded in the amorphous phase, each chain molecule penetrating several crystalline and amorphous regions. If we can assume that the both phases are perfect and that the elasticity and relating relaxation phenomena are exclusively attributed to that of the amorphous phase, then the reducibility of the crystalline polymers will be reduced to that of the purely amorphous polymers. But we should remember that the two phase description of crystalline polymers is only a convention, and that there should be at least intermediate regions between the two limiting phases. In other words, if we consider a representative chain in amorphous region the friction force suffered by segments of the chain will change along with chain length so that the friction tensor ζ in this case also will not be expressed in the simple form of Eq. (42).

e) The relaxation spectrum of dynamic bulk modulus. The linear amorphous polymers are shown to exhibit the dispersion in the bulk modulus as well as in the shear modulus.[15] This is attributable to the cor figurational relaxation of a chain just as i the shear relaxation.[16] It should be re membered, however, that there is an apprec able change of internal energy accompanie by the volume change, so that the operat L_i (Eqs. (33), (36)) can not be neglected. More over the bulk modulus is not expressed in simple form of Eq. (22). These circumstance together will interfere with the reducibilit of the spectrum of the bulk modulus.

§ 6. Discussions

In the above treatments we have ascribe the molecular basis of the time-temperatur reducibility defined macroscopically by Eq (7) and (8) (i.e. the macroscopic reducibilit to the reducibility of the distribution functio of the structural unit, Eqs. (23) and (24) (i. the microscopic reducibility). It is obviou that the latter yields a sufficient but not neces sary condition for the former, except whe all macroscopic quantities of the system whic can be expressed in the simple form of Ec (22) would satisfy the reducibility. Thoug comparative experimental investigations c various relaxation phenomena have not bee made thoroughly, Ferry et. al[17] found tha shift factors $\alpha(T)$'s, of the dynamic and d electric relaxations in many polymers coincid with fairly good precision. This fact seem to give us a resonable, though not sufficien evidence to presume that the macroscopi reducibility is originated from the microscopi reducibility.

We can imagine in Eq. (35) or (36) the cas where $v_m \neq 0$ with div $v_m f=0$, or $F_i \neq 0$ wit div $F_i f_1=0$. But these odd cases mean phys cally that the occurrence of the flow v_m c the force F_i does not give any effective in fluence on the dynamical behavior of th system, so that they will belong to trivia cases, and we shall not go into further detai of them.*)

Structure of Nuclear Quadrupole Resonance Line

II. Solid Bromine

By Shoji KOJIMA, Yoshihito ABE, Midori MINEMATSU, Kineo TSUKADA* and Akira SHIMAUCHI**

Department of Physics, Tokyo University of Education Otsuka, Tokyo

(Received June 26, 1957)

Broad resonance lines of Br^{79} and Br^{81} in a single crystal of bromine have been studied. If the theory of indirect spin-spin coupling is applied, ten components are expected for each lines even when asymmetry of the field gradient tensor is neglected. The observed derivative curves of the lines could not be resolved into more than three lines. Provided that the each components have a finite line width a rough agreement was obtained with the interaction constant of 3 kc. This value is resonable if the s-character of Br–Br bond is 18%. The ratio between overall line width of Br^{79} and Br^{81} accorded approximately with the ratio of the square of nuclear magnetic moment.

§1. Introduction

In a earlier report it was shown that nuclear quadrupole resonance lines in solid iodine, bromine and iodine monochloride have a fine structure which was probably arisen from electron-coupled spin-spin interaction¹⁾. The preceding paper, **I** of this series, has dealt with a detailed measurements of the splitting of the resonance line of solid iodine²⁾. The present paper contains an extension of that measurement to solid bromine, whose crystal structure is the same as iodine. Solid bromine contains two isotopes, Br^{79} and Br^{81}, with nearly equal abundances and the spin numbers of both isotopes are 3/2, whereas iodine consists of single isotope having spin of 5/2. An investigation of bromine seems to be interesting in the fact that splittings due to the indirect spin-spin interaction are simpler than iodine owing to smallness of the spins. Moreover, comparison between the splittings of both isotopes will be valuable to verify the origin of the splitting.

** Now at Institute for Optical Research, Tokyo University of Education, Shinjuku-ku Tokyo.

Sometimes spurious complex patterns of resonance lines were observed for a number of compounds when the samples were locally heated by radio-frequency field. Such cases are described in the Appendix. Iodine monochloride is also discussed there.

§ 2. Experimental Procedures

Bromine used was purified by means of dehydration and distillation from a commercial sample. The purified sample was kept from moisture, otherwise it showed no fine structure of the resonance line. A single crystal of bromine was produced by the method of pointed-bottom crucible, which was used in the previous experiment on the Zeeman effect of bromine[3)].

The detector was a super-regenerative detector with a transmission line tuned circuit as previously[3)]. The transmission line, however, was extended to about one wave length, so that the sample was located far from the vacuum tubes. The recording system was the same as discribed in **I**.

The crystallographic axes of bromine were determined through the method of Zeeman effect of nuclear quadrupole resonance with larger Helmholz coil than that of the previous experiment. The Helmholz coils consisted of air cooled coils with separation of 11 cm. Each coil had inner diameter of 25 cm, outer diameter of 35 cm and thickness of 4.3 cm with 5000 turnes of No. 24 enamelled copper wire. These coils were mounted in a goniometer.

§ 3. Result of Experiments

The absorption curve of Br^{81} was observed by an oscilloscope with large modulation of frequency. The observed pattern is reproduced in Fig. 1. In order to keep the sample at constant temperature this observation was made at the melting point of bromine of −7.9°C, while a small part of sample was melting. Although the large modulation of frequency gave rise to distortion of pattern, the observed curve showed a complex structure. By using small modulation a derivative curve was recorded which showed complex structure more decidedly (Fig. 2). The obtained pattern could be resolved into three lines.

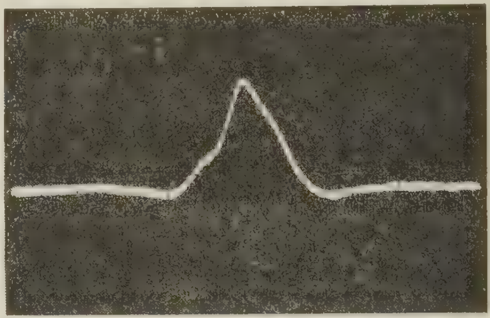

Fig. 1. Absorption curve of Br^{81} at −7.9°C.

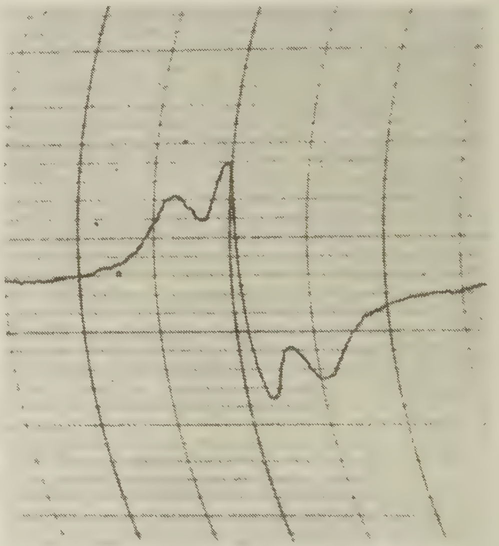

Fig. 2. Derivative curve of Br^{81} at −7.9°C. Frequency increases from the left to the right.

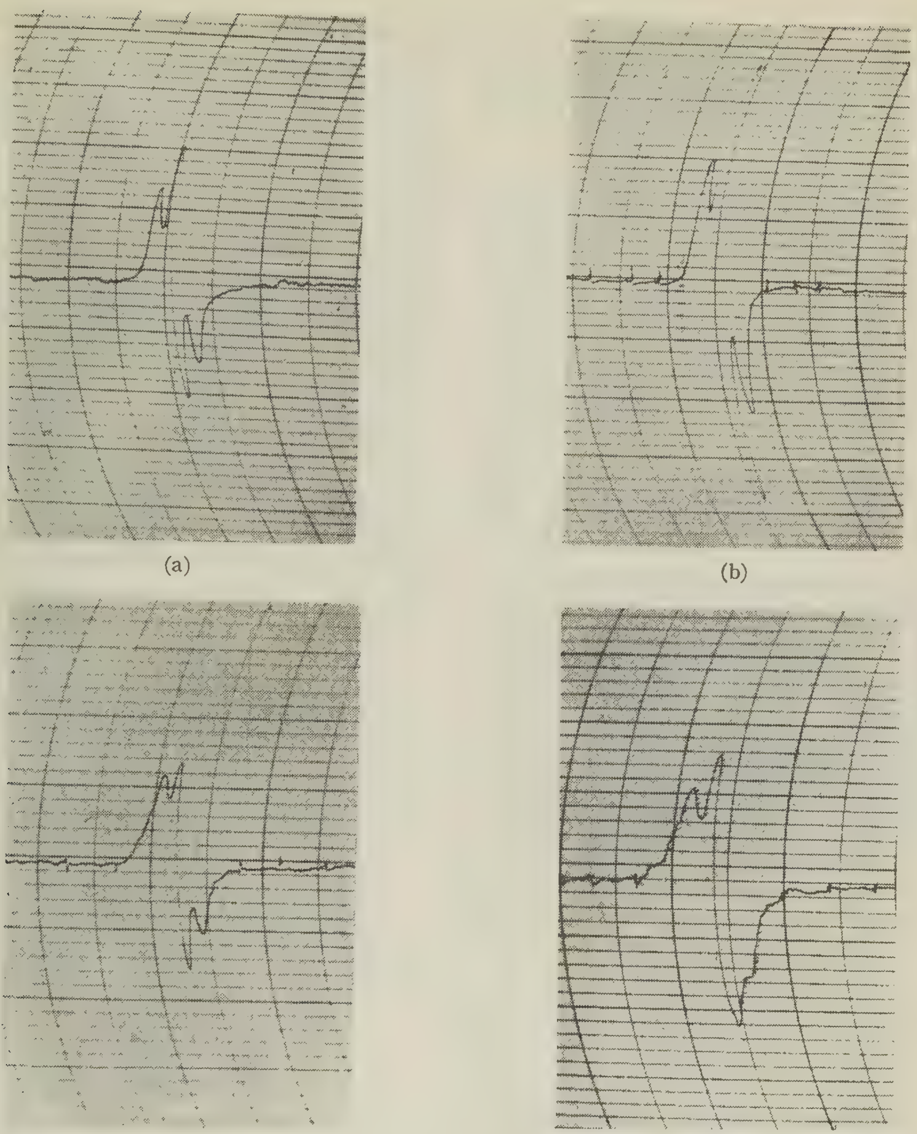
Since the previous experiment on the single crystal of iodine revealed that the pattern of the absorption line depended on the orientation of the applied radio-frequency field. The pattern had to be studied at various orientatio of the rf field with a single crystal whose crystallographic axes were determined. In order to carry out many measurements with one single crystal the experiment at the melting point of the sample is unfavourable. Then the following experiments were carried out at



(a)　(b)

(c)　(d)

Fig. 3. Derivative curves at −23°C.

(c) Br^{81}. The rf field parallel to the *c* axis.
(d) Br^{79}. The rf field parallel to the *a* axis.

−23°C which was the melting point of carbon-etra-chloride.

Derivative curves of the resonance line of r^{79} and Br^{81} were recorded at various orienta-ions of the rf magnetic field. Their frequ-encies were about 378 Mc and 315 Mc respec-ively. Some of the recordings are reproduced n Fig. 3. The curve Fig. 3 (a) agreed well ith the curve of Fig. 2. The over-all split-ings of the patterns of Br^{79} and Br^{81} are 21.0 ±0.5 kc and 24.0±0.5 kc respectively. These were determined as the spreading between two outer peaks of the derivative curves.

Shapes of absorption curves can be obtained by integrating the derivative curves. As an example, a curve which was obtained by graphical integration is shown in Fig. 4.

§ 4. Calculation of the Splitting

Theory of the electron coupled spin-spin interaction in solid iodine was recently given by Itoh and Kambe[4]. By their theory the Hamiltonian of the interaction is expressed by*,

$$\mathscr{H}_{\text{int}}=J\boldsymbol{I}_{1z}\boldsymbol{I}_{2z}+K(\boldsymbol{I}_{1x}\boldsymbol{I}_{2x}+\boldsymbol{I}_{1y}\boldsymbol{I}_{2y})\,, \tag{1}$$

where $\boldsymbol{I}_1$ and $\boldsymbol{I}_2$ are spins of a pair of nuclei in a molecule. The interaction constants J and K are,

$$J=\frac{2\hbar^2}{\Delta E}\left[\beta\gamma\left\{\frac{8\pi}{3}\alpha|\psi(0)|^2+\frac{4}{5}(1-\alpha)\left\langle\frac{1}{r^3}\right\rangle\right\}\right]^2,$$
$$K=\frac{2\hbar^2}{\Delta E}\left[\beta\gamma\left\{\frac{8\pi}{3}\alpha|\psi(0)|^2-\frac{2}{5}(1-\alpha)\left\langle\frac{1}{r^3}\right\rangle\right\}\right]^2, \tag{2}$$

In this expression α is the s-character of the chemical bond, β the Bohr magneton, γ the gyro-magnetic ratio of the nucleus and ΔE is the mean energy difference of excited states from the ground state. $|\psi(0)|^2$ is approximately expressed by $Z\delta^2/\pi n' a_0^3$ where Z is the atomic number, δ Slater's orbital exponent, n' the effective principal quantum number and a_0 is the Bohr radius. For bromines Z, δ and n' are 35, 1.65 and 3.7 respectively. $\langle 1/r^3\rangle$ can be obtained from the coupling factor of hyperfine structure of $^2P_{3/2}$ term. By King and Jaccarino[5] the factor, $\frac{16}{15}\beta\gamma\frac{1}{2\pi}\left\langle\frac{1}{r^3}\right\rangle$, of Br^{79} and Br^{81} are given as 884.810 Mc and 953.770 Mc respectively.

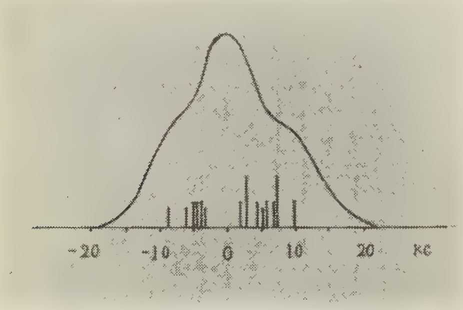

Fig. 4. Integrated curve obtained from the curve (a) in Fig. 3. The line spectrum is calculated from the theory assuming that $J\approx K=3$ kc.

Splitting of the nuclear quadrupole energy levels were calculated by perturbation theory started from the eigenstates $\psi_{m_1}\psi_{m_2}$, where m_1 and m_2 refer to the magnetic quantum numbers of the two spins. The splittings are different between homonuclear molecules, Br^{79} Br^{79} and $\text{Br}^{81}\text{Br}^{81}$, and heteronuclear molecule $\text{Br}^{79}\text{Br}^{81}$, on account of mixing and nonmixin of the states $\psi_{3/2}\psi_{1/2}$ and $\psi_{1/2}\psi_{3/2}$. The resu of calculation by the first order perturbatio theory is shown schematically in Fig. 5, wher asymmetry of field gradient tensor is neglect ed for simplicity. Transitions are allowed i $\Delta m_1=\pm 1$, $\Delta m_2=0$ and if the character of sym metry for exchange of nuclei is conserve As shown in Fig. 5, five resonance lines ar expected for both types of molecule**. Relative intensities of these five lines a, b, c, and e are 2:2:1:1 and 2 for both types o molecules. The lines are independent o orientations of the rf field at this stage o approximation.

Fig. 5. Energy level diagram.

The quadrupole interaction of solid bromine is known to have a small deviation from axia symmetry. The asymmetry parameter define by $\eta=(q_{xx}-q_{yy})/q_{zz}$ was experimentally deter mined as -0.20[3]. This effect is accounte by the additional Hamiltonian;

$$\mathscr{H}_{\text{asy}}=\eta\left\{\frac{h\nu_1}{6}(\boldsymbol{I}_{1x}{}^2-\boldsymbol{I}_{1y}{}^2)+\frac{h\nu_2}{6}(\boldsymbol{I}_{2x}{}^2-\boldsymbol{I}_{2y}{}^2)\right\}, \tag{3}$$

---

* Eq. (1) in the paper I was misprinted. $AI_1I_2+B(I_{1x}I_{2x}+I_{1y}I_{2y})$ should be read $AI_{1z}I_{2z}+B(I_{1x}I_{2x}+I_{1y}I_{2y})$.

** The resonance frequencies are given in Eqs (4) and (5), by putting $\eta=0$.

where ν_1 and ν_2 are the resonance frequencies of nuclei 1 and 2. Splittings of energy levels were calculated by the second order perturbation theory. In this calculation, however, the small terms containing K^2, J^2 and η^2 were omitted. The result for the heteronuclear molecules shows that the two degenerate states $\psi_{\pm 3/2}\psi_{\mp 1/2}$ and $\psi_{\pm 1/2}\psi_{\mp 3/2}$ split each into a pair of states having additional energy of $\pm\eta K$ and that the states $\psi_{\pm 1/2}\psi_{\pm 1/2}$ into a pair states of $\mp 2\eta K$. The first state of the pairs is represented by a symmetric wave function with respect to the reflection by the *ac*-plane and the second by an antisymmetric one. In the homonuclear molecules the splitting of the states $\psi_{\pm 1/2}\psi_{\pm 1/2}$ is the same as the heteronuclear molecules, but the degenerate state which are represented by four eigen function $\psi_{\pm 3/2}\psi_{\mp 1/2}$ and $\psi_{\pm 1/2}\psi_{\mp 3/2}$, split into three states having the additional energy of $2\eta K$, 0 and $-2\eta K$* with the character of $(+, e)$, $(\pm, o)$ and $(-, e)$ respectively, where e and o indicate the even and odd character of exchange of nuclei and $\pm$ the symmetric character respect to the reflection by the *ac*-plane.

The resonance frequencies expected from these levels are expressed by

$$\left.\begin{aligned}
\nu_a &= \nu_o + (3/2)J\,, \\
\nu_{b_1}, \nu_{b_2} &= \nu_o + (1/2)J \pm 2\eta K\,, \\
\nu_{c_1}, \nu_{c_2} &= \nu_o - (1/2)J + 2K \pm \eta K\,, \\
\nu_{d_1}, \nu_{d_2} &= \nu_o - (1/2)J - 2K \pm \eta K\,, \\
\nu_{e_1}, \nu_{e_2} &= \nu_o - (3/2)J \pm \eta K\,,
\end{aligned}\right\} \qquad (4)$$

for heteronuclear molecules and

$$\begin{aligned}
\nu_{a'} &= \nu_o + (3/2)J - (3/2K)\,, \\
\nu_{b_1'}, \nu_{b_2'} &= \nu_o + (1/2)J + (3/2)K \pm 2\eta K\,, \\
\nu_{c'} &= \nu_o - (1/2)J + 2K\,, \\
\nu_{d_1'}, \nu_{d_2'} &= \nu_o - (1/2)J - 2K \pm 2\eta K\,. \\
\nu_{e_1'} &= \nu_o - (3/2)J\,, \\
\nu_{e_1'}, \nu_{e_3'} &= \nu_o - (3/2)J \pm 2\eta K\,.
\end{aligned} \qquad (5)$$

for homonuclear molecules.

Relative intensities of lines, a, b_1, b_2, c_1, c_2, d_1, d_2, e_1 and e_2 are 2:1:1:Y:X:X:Y:1:1 where $X=\cos^2\theta$ and $Y=\cos^2\phi$ being θ the angles between the rf field and the X axis and ϕ the angle between the rf field and the Y axis of field gradient tensor**. For lines a', b_1', b_2', c', d_1', d_2', e_1', e_2' and e_3', relative intensities are 2:1:1:1:X:Y:1:Y:X.

§ 5. Analysis of the Resuls

The observed spectrum on Br^{81} is the mixing of spectrum of homonuclear molecule $Br^{81}Br^{81}$ and that of heteronuclear molecules $Br^{79}Br^{81}$ with nearly equal intensities. Taking into account the difference between the values of the magnetic moments of Br^{79} and Br^{81}, 18 lines are expected from the calculation. The theoretical spectrum is a function of the ratio of K/J. The line spectrum shown in Fig. 4 is calculated with $J \approx K \approx 3$ kc. On the other hand, the observed spectrum could not be resolved into more than three lines because of a finite width of each lines. Therefore, exact comparison between theory and experiment is impossible. If we assume that *s*-character of the Br–Br bond is 18%***, we can calculate J and K by using Eq. (2). The calculated values of J and K are 2.9 kc and 0.46 kc for Br^{81}. The obtained spectrum, however, shows poor agreement with the observed one. If we assume that $J \approx K \approx 3$ kc as the case of iodine, better agreement is obtained than the previous case, although some discrepancies still remain. In this case, in order to fit the spreading of the observed pattern the width of the each components must be about 15 kc.

The ratio of overall splitting of the resonance of Br^{79} to Br^{81} is about 1.14. This value accords approximately with the ratio of the square of nuclear magnetic moment****, 1.16, and does not with the ratio of the nuclear quadrupole moment. If the splittings were arisen from nonequivalent position of nuclei, the splitting would be proportional to the nuclear quadrupole moment. The dependence of the spectrum in bromine upon the orientation of rf field is less than in the case of iodine. The reason is that the pairs of lines, which have the intensity X and Y, are near each other and cancel the effect.

---

* For homonuclear molecules the energies of levels are also calculable by using the general formula derives by Itoh and Kambe, *i.e.*, Eq. (22) of Ref. (4).

** When the character of asymmetry for the reflection to the *ac*-plane changes, the intensity is proportional to Y and when it does not change, the intensity is proportional to X.

*** R. S. Mulliken (J. Am. Chem. Soc. **77** (1955) 884) estimated theoretically the *s*-characters of the F_2 molecule and the Cl_2 molecule to be 2% and 10% respectively. T. Itoh and K. Kambe[4)] obtained 22% *s*-character for the I_2 molecule from the analysis of indirect spin-spin interaction.

**** Strictly speaking, when the ratio are taken for the homonuclear molecules. $Br^{79}Br^{79}$ and Br^{81}–Br^{81}, the ratio should agree with the square of the magnetic moment. In the practical case where heteronuclear molecules exist the ratio will be reduced somewhat.

The present results on bromine are summerized in Table I. For comparison, the previous results on iodine are also summerized in the Table.

Table I.

	Br^{79}	Br^{81}	I^{127}
Resonance freq. (Mc)	378	315	332
Overall splitting (kc)	21	24	48
Interaction constant (kc)	2.6	3.0	3.0
s-character of the bond (%)	20	20	22

The mechanism of indirect spin-spin coupling seems adequate to account for the observed structure of the absorption line. The agreement between the observed pattern and the calculated pattern, however, is not satisfactory.

Acknowledgement

The authors wish to thank Dr. K. Kambe and Dr. T. Itoh for valuable advice in theoretical considerations. The present work was partially supported by the Scientific Research Expenditure of the Ministry of Education.

Appendix

It was often experienced that a resonance frequency shifted during observation. This effect resulted from a rise of temperature of samples due to heat conduction from vacuum tubes and to dielectric absorption of radiofrequency power. An experiment on paradibromobenzene with a super-regenerative spectrometer which was operated at high power level demonstrated a temperature rise of about 4°C.

If a sample is so large that its ends extend to outside of the rf-coils, the temperature in the sample will be non-uniform. Non-uniform distribution of temperature may given rise to spurious fine structure of the resonance line. Indeed, a sample of dibromobenzene in a suitable condition showed a broad resonance line having a complex structure. This pattern, however, changed with time. Therefore it could be distinguished from the structure du to indirect spin-spin coupling.

In early experiment on iodine monochlorid a complex resonance line was observed almos stably as shown in Fig. 6. Using a mor pure sample we have repeated the experiment In the present experiment* the resonance lin showed an ordinaly pattern having a width o about 25 kc. The oscillograph display is reproduced in Fig. 7.

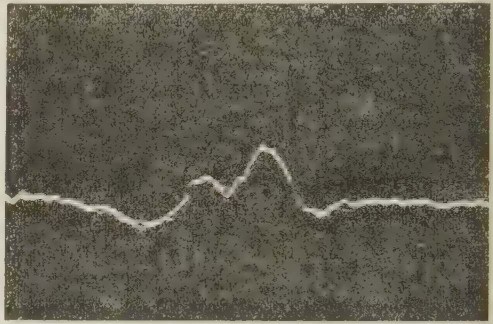

Fig. 6. Complex structure arisen from local heating of sample (ICl).

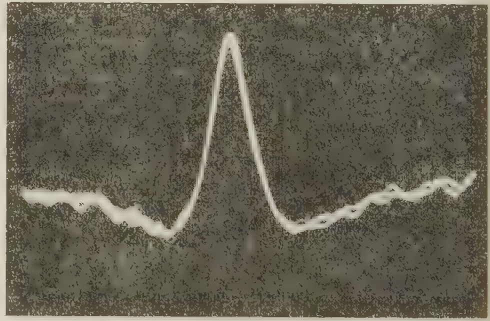

Fig. 7. Absorption curve of I^{127} in iodine monochloride.

Transiently, however, a complex structur Fig. 6 was observed in the present experiment. This pattern was not arisen from th indirect spin-spin interaction, but from th mechanism of local heating. If the crysta used is perfect and in nonstress, the rathe broad width will be accounted from the indirect spin-spin interaction. The coupling however, is much smaller than the cases o bromine and iodine.

Paramagnetic Resonance Absorption in Chromous Sulphate Pentahydrate

By Kazuo Ôno

Institute for Solid State and Chemical Physics, University of Tokyo

(Received July 23, 1957)

The paramagnetic resonance spectra of Chromous sulphate pentahydrate have been analyzed at room temperature for the wavelengths between 0.54 cm and 1.1 cm. The results show that this crystal has a structure similar that of copper sulphate pentahydrate. The observed data have been analyzed by the so-called spin Hamiltonian and the positions and intensities of the absorption lines are adequately explained by a crystalline electric field of rhombic symmetry. The parameters determined have been found to be quite consistent with the values of the spin-orbit coupling constant and spin-spin interaction constant obtained from spectroscopic data. The line width varies from 1 K oer. to 3 K oer. with the direction of the magnetic field and high frequency field and seems to be broader than that expected from magnetic dipolar interaction alone.

1. Introduction

The method of paramagnetic resonance has een developed for a detailed investigation of ıe lowest energy levels of paramagnetic ions ı crystals. This method is the observation f transitions caused by resonance of a high-requency magnetic field at right angle to ıe magnetic field. The consequence absorp-on of energy therefore shows a series of ıaxima as the static magnetic field is varied. y repeating the experiment for a series of ifferent values of the frequency of the high requency field, it is possible to plot out the nergy levels as a function of the static field. ı particular, one can very accurately estimate ıe splitting of the energy levels in the ab-ence of magnetic fields. Then the resonance ata provide valuable information on the bulk roperties of the crystal e.g. susceptibility and pecific heat at very low temperature.

Amongst the common salts of the first (iron) ansition group, the splitting is small in the ase of Cr^{+++}, V^{++}, Mn^{++}, Fe^{+++}, Co^{++}, and Cu^{++} which have been studied in great detail. In the case of Ni^{++}, Cr^{++}, and Fe^{++}, the splittings are generally larger than the energy of the microwave used usually. So the resonance must be observed with rather high frequencies. That is: $NiSO_4 \cdot 7\,H_2O$1)2) shows a resonance at 0.54 cm and 0.66 cm wavelengths but does not at 1.25 cm because it has zero field splitting of about $2\,cm^{-1}$.

Moreover, the Cr^{++} ion is very unstable and has a strong tendency to oxidize, especially in aqeuous solution. Then it is difficult to obtain a large crystal of divalent chromium salt. So few measurements3)4) have heretofore been made of the magnetic properties of the Cr^{++} ion. Only one salt, $Cr(NH_4)_2(SO_4)_2 \cdot 6H_2O$5), has been studied by the paramagnetic resonance method and it was reported that no resonance was observed at 3 cm wavelength.

The present paper describes the paramagnetic resonance spectra found in chromous sulphate pentahydrate at room temperature for wave-lengths between 0.54 cm and 1.1 cm.

The result shows that the fivehold spin degeneracy is completely lifted by the crystalline electric field of rhombic symmetry and the spacing between the adjacent energy levels are found to be 1.94 cm^{-1}, 0.60 cm^{-1}, 6.42 cm^{-1}, and 0.01 cm^{-1}. A brief account of the measurements on this salt has already been given by Ôno et al.[6)]

§ 2. Crystal Preparation

A solution of Cr^{++} salt is rapidly oxidized by atomospheric air and forms a green one of Cr^{+++}. Hence the solution of Cr^{++} must be prepared and treated in an evacuated vessel. The author obtained fairly large crystals of chromous sulphate as follows (See Fig. 1):

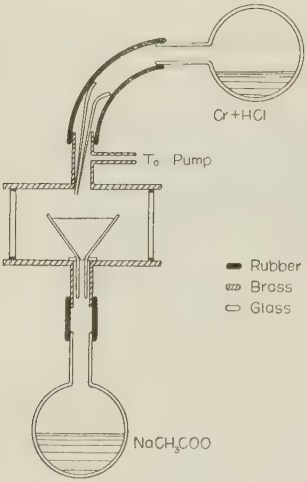

Fig. 1. Apparatus for the preparation of chromous acetate.

A solution of chromous chloride was formed in an evacuated vessel by dissolving chromium metal with hydrochlonic acid. When dissolving was over, the solution was filtered through a paper into a solution of sodium acetate. Chromous acetate, which is sparingly soluble, comes down as red crystals. The chromous acetate was taken out from the vacuum vessel and filtered off in the air because this salt is not oxidized readily.

The chromous acetate was then dissolved in a rather concentrated sulphuric acid in another evacuated vessel and was left overnight. Many crystals were obtained, which have a blue colour, somewhat more violet in tint than that of copper salts. In order that a few well-formed crystals should be obtained it is necessary to ensure that crystal nuclei are not present in too great number. Therefor the filtering of chromous chloride in the evacuated vessel is essential to obtain a goo crystal.

The crystal thus obtained, $CrSO_4 \cdot xH_2O$, i triclinic and the results of resonance absorption show that each unit cell seems to contai two unequivalent ions. The number of wate molecules of crystallization in this crystal wa determined as follows. The weighed crystal were put in a glass tube as shown in Fig. 2 The tube was then evacuated by a mechanica pump, after which the tube was sealed off.

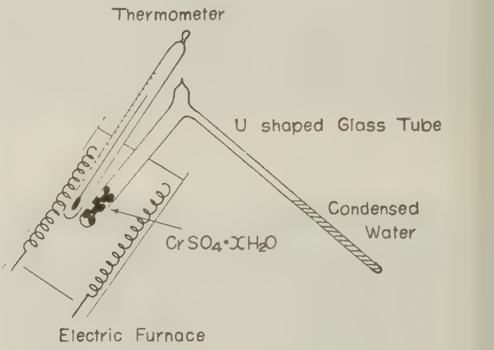

Fig. 2. Apparatus for the determination of the number of water molecules of crystallization i chromous sulphate, $CrSO_4 \cdot xH_2O$.

Then the crystals were heated very slowl keeping the other end of the tube at roo temperature. The hydration water came dow abruptly at about 260°C. The amount o water remained almost constant as the temperature was raised until the unhydrate crystals were decomposed at about 400°C The condensed water of crystallization wa weighed and x was determined to be

$$x = 4.90 \pm 0.50$$

Thus the formula of the crystal becam $CrSO_4 \cdot 5\,H_2O$. It could not be determined readily from the external form of the crysta whether it were isomorphous with coppe sulphate pentahydrate or not.

§ 3. Apparatus and Experimental Procedu

In paramagnetic resonance experiments th advantages of working at shorter wavelength than those used usually ($\lambda = 3$ cm, 1.25 c are;

1) ions with a large zero splitting can investigated;

2) the intensity of absorption goes up as e frequency is raised;
nd 3) measurements can be done by smaller mounts of materials.

Chromous salts has a large initial splitting nd cannot be obtained in a sufficiently large ingle crystal. Then, in the present investiation, it is necessary to use millimeter waveengths.

A crystal multiplier driven by a klystron re frequently used as a source of radiation f the millimeter wave-lengths in micro-wave pectroscopy. But power output from a clytron is quite low, and only second or third armonic is available for physical measureents in solid state spectroscopy, which equires higher power than that in gaseous ne. Since one cannot easily obtain a klytron below the wavelength of 3 cm in Japan, xperiments in millimeter wave region are ifficult.

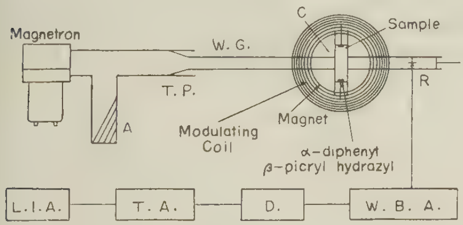

Fig. 3. Schematic diagram of paramagnetic resonance absorption apparatus at millimeter waves employing magnetron harmonics.

It has been reported by Klein et al[7] that nagnetrons emit harmonics of their fundanental frequency of oscillation. Employing he techniques reported by them, harmonics s high as the sixth have been obtained from igh power magnetron. That is: the waveengths used, $\lambda=6.6$ mm and $\lambda=5.4$ mm, were he fifth and the sixth harmonics of the nagnetron of $\lambda=3$ cm.

The main components of the apparatus are hown in Fig. 3. The magnetron is operated vith a pulse length of about one micro-second nd a repetition rate of about 600 per second.

Microwave radiation of the fundamental scillation is reflected back by the tapered iston, T. P., and absorbed by the absorber, . Radiaton of harmonics goes through the vave-guide W. G. The sample crystal is laced at the center of the piston of the ectangular cavity, C. excited in the H_{10n} mode and can be rotated in the plane of the static and micro-wave magnetic field. An external magnet applies a field to the crystal which can be varied from zero to 20 kilogauss. The intensity of the static magnetic field was measured using a fluxmeter and calibrated by the magnetic field for the absorption peak of α-diphenyl β-picryl hydrazyl ($g=2.00$, $\Delta H=$ several gauss) at $\lambda=5.4$ mm. A pair of subsidiary coils wound on the pole-pieces are used to modulate this field to a depth of about 200 gauss at a frequency of 30 c/sec.

The absorption of micro-wave energy by the sample in the cavity reduced the Q-value of the cavity, and was registered as a diminution of the power transmitted. The power is detected by the silicon rectifier, R, which is a demountable one constructed with a silicon wafer and a tungsten cat whisker within the wave-guide. Then the power, modulated with 30 c/sec, is fed through the wide-band amplifier, W.B.A., the detector D, the amplifier, T. A., tuned to the modulation frequency, and the lock-in amplifier, L.I.A. This amplifier output is read on a meter.

The wave-length of $\lambda=11$ mm is obtained by a harmonics multiplier of silicon diode crystal from the fundamental oscillation of a 2K25 klystron. ($\lambda=3$ cm). The measuring method is essentially the same as that of the wavelength of 5.4 mm and 6.6 mm.

The positions of absorption lines vary very rapidly with the direction of the applied magnetic field, and hence with the accuracy of the cutting and mounting of the crystal. The sample used is very small (about 2 mm × 1.5 mm × 0.5 mm) and the accuracy of this process is rather bad.

§ 4. Preliminary Discussion of the Spectrum

Before describing the observed spectrum, it is convenient to consider the theoretical basis for its interpretation.

The free ion Cr^{++} is in a ^5D state but the orbital momentum is strongly quenched by a crystalline electric field. (shown in Fig. 4). The orbital levels are split by a cubic field into a triplet Γ_5 and a doublet Γ_3. The nonmagetic doublet is split by a tetragonal or rhombic field, and paramagnetic resonance is observed for the lower level. The combined effects of the non cubic part of the crystalline field and the spin-orbit coupling then produce a further small splitting of the lowest orbital singlet, which has five fold degeneracy due to the spin ($S=2$).

When static magnetic field is applied this spin quintuplet is approximately descrived by the Hamiltonian

$$\mathscr{H}=\{SD_z^2-1/3\,S(S+1)\}+E(S_x^2-S_y^2)$$
$$-\beta(g_xH_xS_x+g_yH_yS_y+g_zH_zS_z) \qquad (1)$$

The term in D represents the fine structure due to the crystalline field of axial symmetry, while small departures from this due to the rhombic component appear as the term in E. Here g is the spectroscopic splitting factor, β is the Bohr magneton, and $\boldsymbol{H}$ is the applied magnetic field.

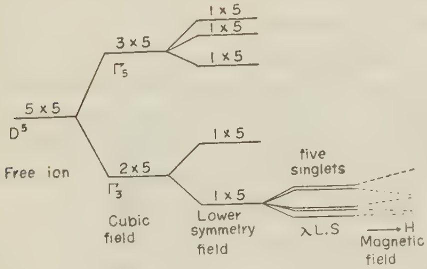

Fig. 4. Schematic energy levels of Cr++ ion in crystalline electric field.

The expressions for the parameters D, E, and g are derived by Koide and Sekiyama;[7)]

$$D=-3(l^2-m^2)\left(\frac{\lambda^2}{\Delta E}+\rho\right) \qquad (2)$$

$$E=-2\sqrt{3}\,lm\left(\frac{\lambda^2}{\Delta E}-\rho\right) \qquad (3)$$

$$\left.\begin{aligned} g_x&=2-2(l-\sqrt{3}\,m)^2\lambda/\Delta E\\ g_y&=2-2(l+\sqrt{3}\,m)^2\lambda/\Delta E\\ g_z&=2-8l^2\lambda/\Delta E \end{aligned}\right\} \qquad (4)$$

where λ is the spin-orbit coupling coefficient, ρ is the spin-spin coupling constant between $3d$ electrons, ΔE is the spacing between Γ_3 and Γ_5, and l and m satisfy the relations

$$\left.\begin{aligned} 2lm/[\sqrt{3}\,(l^2-m^2)]&=E/D\\ l^2+m^2&=1 \end{aligned}\right\} \qquad (5)$$

Spectroscopic data indicated $\lambda=58\,\mathrm{cm}^{-1}$ and $\rho=0.42\,\mathrm{cm}^{-1}$ [8)9)] for the free Cr++ ion. Assuming $E=0$ we have two alternative cases in the above formula, i.e., $l=1$, $m=0$ and $m=1$, $l=0$. Since copper sulphate corresponds to the former, it is resonable to assume that for chromous sulphate it is also the case With the values of $\lambda=58\,\mathrm{cm}^{-1}$, $\rho=0.42$ cm and $\Delta E=10000\,\mathrm{cm}^{-1}$, it is obtained from eq. (and eq. (4) that

$$D=-2\,\mathrm{cm}^{-1} \qquad g_z=1.95 \qquad g_x=g_y=1.99\,.$$

The assumed value of $\Delta E=10000\,\mathrm{cm}^{-1}$ reasonable considering the color of the cryst which is due to transition between Γ_3 and

The levels of the spin quintuplet when $\boldsymbol{H}=$ are seen from (1) to be

$$\left.\begin{aligned} W_1&=-2\sqrt{D^2+(3E)^2}\\ W_2&=-D-3E\\ W_3&=-D+3E\\ W_4&=2D\\ W_5&=2\sqrt{D^2+(3E)^2} \end{aligned}\right\} \qquad (6$$

When $\boldsymbol{H}$ is present, these levels vary wit $\boldsymbol{H}$. In Mn++, Fe+++, and Cr+++, D is sma compared with $g\beta H$ and they can be approx mated by simple formulae, but this is not th case in Cr++.

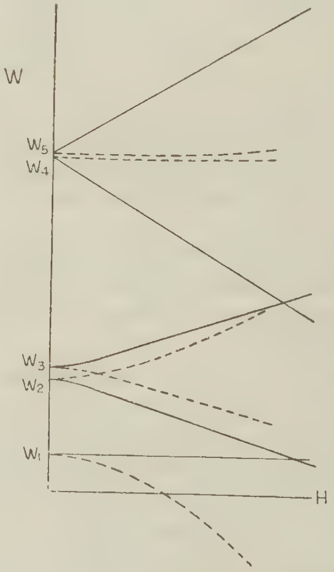

Fig. 5. Relative positions of the lowest energy levels of the Cr++ ion in $CrSO_4\cdot 5H_2O$. The full lines are those for H//z and the dashed lines for H//y.

Fig. 5 shows the calculated values of W using eq. (1) with the values $D=2.24\,\mathrm{cm}^{-}$ $E=0.10\,\mathrm{cm}^{-1}$ and $g_x=g_y=g_z=2.00$. The micro wave transition ($W_2 \leftrightarrow W_1$) can be observe when $\boldsymbol{H}$ is parallel to z and that betwee ($W_2 \leftrightarrow W_3$) when $\boldsymbol{H}$ is applied in the xy plane The transition ($W_2 \leftrightarrow W_3$) is energitically possible in the case of $\boldsymbol{H}//z$, but forbidden b selection rule.

5. Experimental Results

The analysis of the spectrum of chromous ulphate is very complicated with the followng reasons.

1) The value of D is large compared with βH.

2) The structure of this crystal is trinclinic nd magnetic axes bear no relation to the rystalline axes.

3) The spectrum is doubled by the presence of two inequivalent ions in a unit cell.

To determine the constants D, E and g, it requires to be two things.

1) To find directions of the rohmbic axes $x_1y_1z_1)(x_2y_2z_2)$ associated with the dissimilar ons in unit cell.

2) To observe the resonance fields with **H** parallel to any particular rhombic axis for different values of λ, so that the parameters n eq. (1) can be determined.

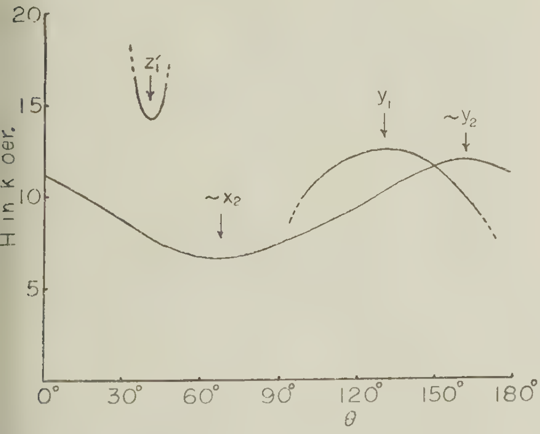

Fig. 6. The angular dependence of the resonance field in the $z_1'y_1$ plane with λ=11 mm. x_1, y_1, z_1 and x_2, y_2, z_2 indicate the rhombic axes of the crystalline fields corresponding to the two kinds of ions, respectively.

It is remembered that the resonance field with **H** parallel to any particular rhombic axis as a maximum or minimum one. For example, one of the rhombic axis, z_1, can be determined precisely as follows.

The crystal is mounted in a cutted plane, say α' plane, which was found to contain z_1' and y_1' nearly parallel to z_1 and y_1, respectively. Fig. 6 shows the resonance field against the direction of **H** in this plane with λ=11 mm. The direction of the minimum value of resonance field **H** corresponds to z_1'. Then the crystal is remounted in a α'' plane which is rotated by about 2 degree about an axis perpendicular to z_1' in the α' plane. The resonance fields near z_1' against **H** were also observed and z_1'' axis was obtained corresponding to the minimum value of **H**. A series of the values of **H** corresponding to z_1', $z_1''\cdots$ thus obtained are plotted against the angle of rotation in Fig. 7. The minimum value of **H** in Fig. 7 corresponds to the true z_1 axis.

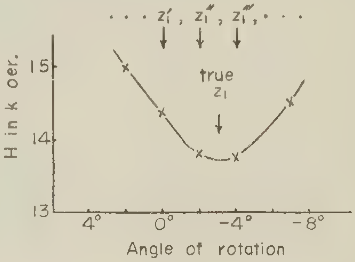

Fig. 7. A series of the values of H corresponding to z_1', z_1'', $\cdots$

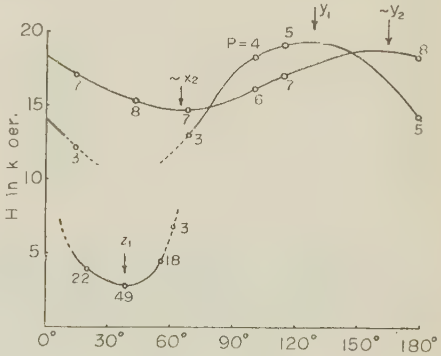

Fig. 8. The angular dependence of the resonance field in the z_1y_1 plane with λ=5.4 mm. Here P is the intensity of the absorption, the product of the muximum absorption and the width of the absorption line.

Thus the positions of absorption lines with **H** parallel to any particular rhombic axis were precisely determined, although the sample used was so small that the accuracy of the cutting and mounting was not sufficient.

Fig. 8 shows the angular dependence of the resonance field in the z_1x_1 plane with λ=5.4 mm and Fig. 9 and Fig. 10 shows that in the z_1x_1 plane and the z_1z_2 plane with λ=6.6mm respectively. We can see in Fig. 10 that the angle between z_1 and z_2 is 86°. This angle is the same as that obtained by the author for copper sulphate pentahydrate. In the figures, the positions where the intensity is low are written with the dashed curves. They disappear with $\boldsymbol{H}$ parallel to z_1 where the transition ($W_2 \longleftrightarrow W_3$) is forbidden by selection rule.

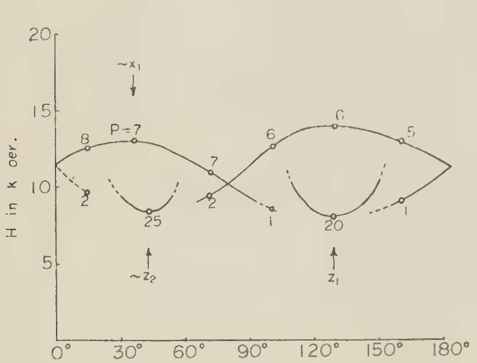

Fig. 9. The angular dependence of the resonance in the z_1x_1 plane with $\lambda=6.6$ mm. Here P is the intensity of the absorption.

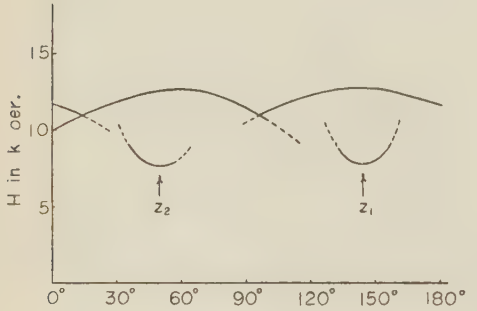

Fig. 10. The angular dependence of the resonance field in the z_1z_2 plane with $\lambda=6.6$ mm.

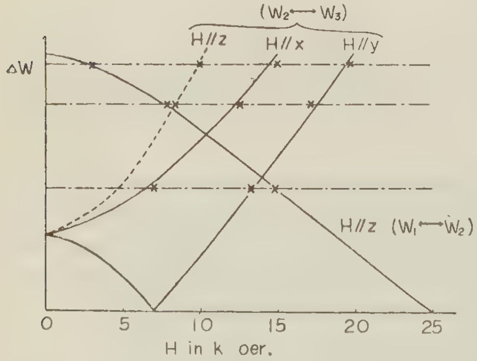

Fig. 11. ΔW as a function of H. The full line indicate the theoretical values and the crosses the experimental ones.

Assuming $g_x=g_y=2.00$, the best fit of the experimental transitions is obtained with $D=2.24\,\mathrm{cm}^{-1}$, $E=0.10\,\mathrm{cm}^{-1}$ and $g_z=1.96$. Fig. 11 shows the calculated values of ΔW (full lines) using these values from eq. (1), and th crosses are the experimental points. Thes values of D and g_z are quite consistent wit those calculated from the eq. (4) using spectro scopic data. With $D=2.24\,\mathrm{cm}^{-1}$ and $E=0.1$ cm^{-1}, it is also obtained from eq. (5) that

$$m=0.035 \quad \text{and} \quad l=1.00\,.$$

For a splitting of the type shown to exist Cr^{++}, the principal susceptibilities for an io with axial symmetry are

$$\left.\begin{aligned} \chi_{\parallel} &= 2Ng_{\parallel}{}^2\beta^2/kT(1-7D/5kT) \\ \chi_{\perp} &= 2Ng_{\perp}{}^2\beta^2/kT(1-7D/10kT) \end{aligned}\right\} \qquad (7)$$

Then, the sign of D may be determined by observing the anisotropy. The contribution to the specific heat from these splittings o the energy levels is given by;

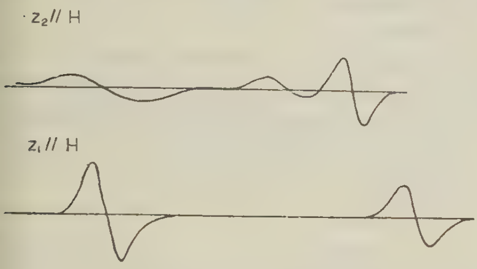
$$CT^2/R=\left(\frac{hc^2}{k}\right)\frac{14}{5}(D^2+3E^2) \qquad (8)$$

The susceptibility of chromous sulphate hexahydrate, $CrSO_4 \cdot 6H_2O$, in a powdered form has been studied by Lips[3]. Over the temperature range 54°K to 400°K he found the Weiss law to be obeyed with an effective Bohr number of 4.82, in agreement with the value of eq. (7) neglecting the D term. Unfortunately, for the lack of data on susceptibility and specific heat at very low temperature, comparison between measured and calculated ones cannot be made.

§ 6. Line Widths

Because of the rather closer spacing of the Cr^{++} ions in the crystal, there may be exchange interaction between identical and non-identical ions as can be seen in the case of $CuSO_4 \cdot 5\,H_2O$(1) which contributes fairly to line widtns. Moreover, the experimental magnetic field is never really large compared with the Stark splitting of the energy levels. So the observed magnetic width is not in general linearly related to the frequency width, and this can have the effect of broadening the observed line, especially in the transition ($W_1 \longleftrightarrow W_2$). Van Vleck has calculated the line width from magnetic dipolar interaction alone. In the crystal, the calculated dipolar width is about 1.3 K oer., but the calculation can not be applied to the case in details from the reasons mentioned above.

The observed widths of absorption lines varied with the orientation of the crystal, rom 1 K oer. to 1.5 K oer. in the transition $W_2 \leftrightarrow W_3$) and from 1.3 K oer. to 3.0 K oer. ı the transition ($W_1 \leftrightarrow W_2$). Fig. 12 shows ıe absorption curves in the z_1x_1 plane with $=5.4$ mm. The error of the broadest line ridth is estimated at 30%～40% on account f low signal to noise ratio, while that of the arrower one is correct within 10%. Line idth does not vary remarkably with wave-ngth and that multiplied by $d(\Delta W)/dH$, erived from Fig. 11, gives almost a constant ith the same orientation of the crystal. The ıape of every absorption line is near to ıussian.



ig. 12. Paramagnetic resonance spectrum of Cr^{++} ion (1) and ion (2) in the z_1z_2 plane with $\lambda=5.4$ mm.

7. The Intensity of the Absorption Lines

The intensity of the absorption lines varied ith the direction of the external field $\boldsymbol{H}$, ith the direction of the oscillating field h, ıd with the wavelengths λ. Fig. 8 and Fig. show relative intensities of absorption in ıe z_1y_1 plane with $\lambda=5.4$ mm and in the z_1x_1 ane with $\lambda=6.6$ mm. In the figures, inten-ty, P, are normalized by an absorption of diphenyl β-picryl hydrazyl mounted in the me measuring cavity containing the crystal. he intensity of the absorption is nearly otropic both with the direction of the exter-ıl field $\boldsymbol{H}$, and the oscillating field h in the plane, while the intensity varies remarkably ith $\boldsymbol{H}$ and h in the plane containing the axis.

A comparison is made in Table I between perimental and calculated transition proba-lities. The theoretical values of relative ansition probabilities between two eigen-ates, 1 and 2, for a single system per unit ne with eigenvalues differing the energy $_0$ for x-polarized radiation is

$$P=(2\pi/\hbar)^2|\mu_{12}{}^x|^2 I\,. \qquad (9)$$

Where $\mu_{12}{}^x$ is the matrix element of the magnetic moment operator $\mu^x=g_x\beta S_x$ and I is the total energy in the incident radiation field per unit volume per unit frequency interval. A conversion must be made, however, because the theoretical probabilities are calculated at the constant field as a function of frequency, while the observations were made at the constant frequency. This is accomplished to a first order by the factor $d(\Delta W/dH)$, the slope of the transition energy curve as a function of magnetic field in Fig. 11. In Table I, $P(z,x)$ refers to the transition probability when $\boldsymbol{H}$ is parallel to z and h is parallel to x, $P(z,X)$ in which large letter X is used instead of small one x or y is calculated with $E=0$, and $\widehat{xy}$ indicates the bisector of x and y. Here experimental transition probability means the product of the maximum absorption and the width of the absorption line. The agreement between experimental and calculated values is fairly good.

Table I. Comparison of experimental and theoretical transition probabilities. For the notation used see the text.

transition probabilities observed	λ mm	expt. ratio	theor. ratio.

A Semi-empirical Theory of the Conjugated Systems

I. General Formulation

By Yuzuru Ooshika

Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received July 23, 1957)

A general semi-empirical theory of conjugated double bond systems, including those with non closed-shell structures and heteroatoms, is developed. The general formulation is similar with that of Pariser and Parr and that of Pople and others, but for non closed-shell structure our equations are somewhat different from those of Pople et al. The necessary parameters for hydrocarbons, which have previously been determined arbitrarily as the case may be, are estimated, in the present paper, by using the experimental data of the ethane and ethylene molecules. The theory is checked by some simple examples and found to be in satisfactory agreement with experiments.

§1. Introduction

One of the most interesting branches in the field of the molecular physics, so-called the π-electron theory of the conjugated double bond systems, has been developed by many investigators and an enormous number of papers have been published in later years. The theoretical basis of such π-electron theory was discussed by Lykos and Parr[1], and we shall limit our discussion in the π-electron approximation. General properties of such conjugated systems were thoroughly discussed by various authors, especially by English school, on the basis of the simple L.C.A.O. molecular orbital theory and many useful methods and definitions are introduced, which may be regarded as a theoretical basis of the "electr nic theory of organic chemistry".

In the simple molecular orbital theory, t electronic interactions are taken account only in terms of a suitable average potenti but their explicit consideration is very impo tant both from the theoretical and the pra tical point of view. Of course, in relative simple systems, calculations can be alwa carried out on the exact non-empirical bas including electronic interactions, but, in co plex systems, non-empirical such approa faces prohibitory difficulty due to the labor computation. Thus, in recent years, attemp have been made to develop semi-empiric methods of calculation including electron

teractions, which are practically applicable
› complex molecules.

Pariser and Parr[2] proposed such a semi-
npirical method, where they neglected dif-
rential overlapping between atomic orbitals
ntered about different nuclei for the calcu-
tion of electronic repulsion integrals com-
etely and, among necessary integrals for the
ediction of energy levels, only $(aa|aa)$ and
$a|bb)$ types of integrals were calculated by
sing a simple model. Thus, their method
as successfuly applied to many condensed
ydrocarbons and heterocyclics, probably due
the large reduction of the configulation
teraction. But, in their treatment, the re-
nance integral, β, still remains an adjus-
ble parameter. On the other hand, Pople,
onguet-Higgins and others developed a semi-
npirical theory in the self-consistent scheme[3],
d discussed a wide range of properties in
njugated systems, i.e., ionization potentials,
sorption energies, inductive and mesomeric
fects, etc. Their method of calculation of
e integrals is more or less similar to that
Pariser and Parr. In the present paper,
e shall develop a general semi-empirical
eatment of the L.C.A.O.M.O. type on π-
ectron systems, which will be easily appli-
ble for any complex molecule at a suitable
ep of approximation and in which all the
rameters that we shall not neglect will be
iquely determined by using the experimen-
l data on the simple molecules, and we shall
ow various applications to discussions on
emically interesting properties of conjuga-
d molecules.

2. Forms of Matrix Elements

Before we derive the general S.C.F. equations for the π-electron systems, we shall formulate the hamiltonian matrix elements, when we take a linear combination of Slater determinants as the electronic wave function, into a favorable form for us, though the general formulation has already been given in many literatures[4].

We take a linear combination of antisymmetrized products of orthonormalized one-electron functions (orbital function × spin function)

$$\Phi = \Sigma a_p \Psi_p ,$$

$$\Psi_p = \frac{1}{\sqrt{N!}} \det|\phi_1{}^p(1)\phi_2{}^p(2)\cdots\phi_N{}^p(N)| , \quad (1)$$

$$\int \phi_i(1)\,\phi_j(1) d\tau_1 = \begin{cases} 1 , & \phi_i \equiv \phi_j , \\ 0 , & \phi_i \not\equiv \phi_j \end{cases}$$

as the approximate electronic wave function. The approximate hamiltonian for an N- electron system is, neglecting the magnetic and the nuclear multipole interactions,

$$\boldsymbol{H} = \sum_{i=1}^{N} H(i) + \sum_{i,j} \frac{e^2}{r_{ij}} + H_0 ,$$

where H_0 is the part independent upon the electronic coordinates. The hamiltonian matrix elements are to be linear combinations of such terms as

$$\int \Psi_p{}^* \boldsymbol{H} \Psi_q d\tau_1 \cdots d\tau_N .$$

We can now rearrange the one-electron functions in Ψ_p and can make the maximum number of $\phi_i{}^p$'s in Ψ_p to coincide with $\phi_i{}^q$'s in Ψ^q. Thus, we may assume that

$$\phi_i{}^p \equiv \phi_i{}^q , \quad 1 \leq i \leq N - N_{pq} ,$$

$$\phi_i{}^p \not\equiv \phi_i{}^q , \quad N - N_{pq} < i \leq N .$$

We, then, obtain by a straightforward calculation

$$\int \Psi_p{}^* \Sigma H(i) \Psi_q d\tau_1 \cdots d\tau_N$$

$$= \frac{(-1)^{P_{pq}}}{(N-1)!} \Big\{ (N-N_{pq}-1)(N-N_{pq}-2)\cdots(1-N_{pq}) \sum_l{}' \int \phi_l{}^{p*} H \phi_l{}^q d\tau$$

$$+ (N-N_{pq})(N-N_{pq}-1)\cdots(2-N_{pq}) \sum_l{}'' \int \phi_l{}^{p*} H \phi_l{}^q d\tau \Big\} , \quad (2)$$

here $\sum_l{}'$ means the sum over l where $\phi_l{}^p \equiv \phi_l{}^q$ and $\sum_l{}''$ means the sum over l where
$^p \not\equiv \phi_l{}^q$,

$$\int \Psi_p{}^* \Big(\sum_{ij} \frac{e^2}{r_{ij}} \Big) \Psi_q d\tau_1 \cdots d\tau_N$$

$$= \frac{(-1)^{P_{pq}}}{2(N-2)!} \Big\{ (N-N_{pq}-2)\cdots(1-N_{pq}) \sum_l{}' \sum_k{}' \Big(\iint \phi_l{}^{p*}(1)\, \phi_k{}^{p*}(2) \frac{e^2}{r_{12}} \phi_l{}^q(1) \phi_k{}^q(2) d\tau_1 d\tau_2$$

$$
\begin{aligned}
&-\iint \phi_l^{p*}(1)\, \phi_k^{p*}(2) \frac{e^2}{r_{12}} \phi_k^q(1)\phi_l^q(2)d\tau_1 d\tau_2 \Big) \\
&+2(N-N_{pq}-1)\cdots(2-N_{pq}) \sum_l{}' \sum_k{}'' \Big(\iint \phi_l^{p*}(1)\phi_k^{p*}(2) \frac{e^2}{r_{12}} \phi_l^q(1)\phi_k^q(2)d\tau_1 d\tau_2 \\
&-\iint \phi_l^{p*}(1)\phi_k^{p*}(2) \frac{e^2}{r_{12}} \phi_k^q(1)\phi_l^q(2)d\tau_1 d\tau_2 \Big) \\
&+(N-N_{pq})\cdots(3-N_{pq}) \sum_l{}'' \sum_k{}'' \Big(\iint \phi_l^{p*}(1)\phi_k^{p*}(2) \frac{e^2}{r_{12}} \phi_l^q(1)\phi_k^q(2)d\tau_1 d\tau_2 \\
&-\iint \phi_l^{p*}(1)\phi_k^{p*}(2) \frac{e^2}{r_{12}} \phi_k^q(1)\phi_l^q(2)d\tau_1 d\tau_2 \Big) \Big\} ,
\end{aligned}
$$

and

$$
\begin{aligned}
&\int \Psi_p^* H_0 \Psi_q d\tau_1 \cdots d\tau_N \\
&= \frac{(-1)^{P_{pq}}}{N!} \{(N-N_{pq}-1)\cdots(1-N_{pq})\rho'^{pq}(1, 1)+(N-N_{pq})\cdots(2-N_{pq})\rho''^{pq}(1, 1\} H_0 ,
\end{aligned}
$$

$$\rho'(1, 2)=\sum_l{}' \phi_l^{p*}(1)\phi_l^q(2) ,$$

$$\rho''(1, 2)=\sum_l{}'' \phi_l^{p*}(1)\phi_l^q(2) ,$$

where P_{pq} is the ordinal number of the permutation for coinciding the maximum number of one-electron functions in Ψ_p with those in Ψ_q.

§ 3. Self-Consistent Field Equations for π-Electron Systems

Roothaan[5)] derived the self-consistent field equations in the L.C.A.O.M.O. scheme for the closed-shell configuration in quite a general way, and we have only to simplify his equations so as to apply to our semi-empirical scheme. For the ground state of neutral non-radical molecules, this procedure is expected to give favorable results because of the uniformity of the electronic density pointed out by Longuet-Higgins[6)]. For the non closed-shell excited or ionized states, we shall construct the electronic wave functions conveniently by assigning the electrons to various real and virtual orbitals obtained from the ground state S.C.F. equations, since, if solving the S.C.F. equations for the particular excited states separately, the problem of the orthogonality between the wave functions would complicate the calculations extremely, and since the results obtained by this troublesome procedure would not be expected to be more favorable than those obtained by the simpler procedure. In this respect, Mulliken[7)] showed that the ionization potential calculated by using the same one-electron orbitals as in the groun state also for the ionized state was in close agreement with the experiment than that ob tained by solving the S.C.F. equations sep rately.

There are some interesting systems tha have non-closed-shell ground states, i.e., rad cals, and, in later parts of this series, w shall intend to construct a larger conjugate system from the smaller ones, of which w assume that we have solved the S.C.F. equa tions already, and some of which are of th free radical character. So, we shall deriv a kind of S.C.F. equations for those non close shell structure as well as for the closed-she structure in the L.C.A.O.M.O. scheme of th π-electron systems. Pople and others[3f,g,h)] pr posed a form of S.C.F. equations for the electron systems with non closed-shell stru ture, but, here, we shall take a somewha different procedure from that of Pople an others.

We take as the molecular orbitals for electrons

$$\psi_l=\sum_a c_{la}\psi_a ,$$

where ψ_a is the normalized real $2p\pi$ atom orbital of the a-th atom. The coefficient c is to be determined by the S.C.F. metho We neglect the differential overlapping ψ_a^* between atomic orbitals centered about diffe ent nuclei except in the resonance integr between neighboring orbitals, ar Pariser an Parr, and Pople did. Thus,

$$\sum_a |c_{la}|^2 = 1\ ,$$

$$\int \psi_a H \psi_b d\tau = \beta_{ab}\ , \quad \text{if } a,\ b \text{ neighbor}\ ,$$

$$= 0\ , \quad \text{if } a,\ b \text{ non-neighbor}\ .$$

ere, $H(i)$ is the effective potential for the th electron from the atomic core skeleton, nd we assume it to be of the form

$$H(i) = \sum_a H_a(i)\ .$$

i. Closed shell structure

In this case, the necessary equations were already given by Pople and we shall only rewrite them in our notations and approximations. Assume that $2n$ electrons occupy the molecular orbitals $\psi_1, \cdots, \psi_n$ doubly. Denote the one-electron spin wave functions α and β. Then the electronic wave function is

$$\Phi = \frac{1}{\sqrt{(2n)!}} \det|\psi_1(1)\alpha(1)\psi_1(2)\beta(2)\cdots\psi_n(2n)\beta(2n)|\ . \tag{5}$$

nergy integral for this configuration is given by

$$\mathscr{E} = \int \Phi^* \boldsymbol{H} \Phi d\tau_1 \cdots d\tau_{2n}$$

$$= 2\sum_{l=1}^{n}\sum_a c_{lu}^* c_{la}\left\{-I_a + \frac{1}{2}\sum_{k=1}^{n} c_{ka}^* c_{ka}(I_a - E_a) - \sum_{b \neq a}\left(\frac{Z_b e^2}{R_{ab}} - \sum_{k=1}^{n} c_{kb}^* c_{kb}\frac{e^2}{R_{ab}}\right)\right\}$$

$$+ 2\sum_{l=1}^{n}\sum_a \sum_{b \neq a} c_{la}^* c_{lb}\left\{\beta_{ab} - \frac{1}{2}\sum_{k=1}^{n} c_{kb}^* c_{ka}\frac{e^2}{R_{ab}}\right\} + H_0\ , \tag{6}$$

here, as we wish to estimate various inte- rals in terms of empirically obtained quan- ty, we used the following approximations:

$$\int \psi_a H_a \psi_a d\tau = -I_a\ , \tag{7}$$

$$\iint \psi_a(1)\psi_a(2)\frac{e^2}{r_{12}}\psi_a(1)\psi_a(2)d\tau_{12} = I_a - E_a\ , \tag{8}$$

$$\int \psi_a H \psi_b d\tau = \beta_{ab} = \beta_{ba}\ , \tag{9}$$

$$\int \psi_a H_b \psi_a d\tau = -\frac{Z_b e^2}{R_{ab}}\ , \tag{10}$$

$$\iint \psi_a(1)\psi_b(2)\frac{e^2}{r_{12}}\psi_a(1)\psi_b(2)d\tau_{12} = \frac{e^2}{R_{ab}}\ . \tag{11}$$

and E_a are the 'ionization potential' and e 'electron affinity' of the atom a in the propriate valence state, respectively, Z_a is e number of the formal positive charges of e atomic core, and $1/R_{ab}$ does not mean the verse interatomic distance, $1/r_{ab}$, but is a itable function of r_{ab}, which will be given a later part of this paper. β_{ab} is assumed be determined by the species of atoms a d b and the interatomic distance, which, in rn, should be determined by the bond order neglecting the effects of the formal charge. us, by the variational method, the S.C.F. equations are

$$c_{la}\left\{-I_a + \sum_{k=1}^{n} c_{ka}^* c_{ka}(I_a - E_a)\right.$$

$$\left. - \sum_{b \neq a}\left(\frac{Z_b e^2}{R_{ab}} - 2\sum_{k=1}^{n} c_{kb}^* c_{kb}\frac{e^2}{R_{ab}}\right)\right\}$$

$$+ \sum_{b \neq a} c_{la}\left\{\beta_{ab} - \sum_{k=1}^{n} c_{kb}^* c_{ka}\frac{e^2}{R_{ab}}\right\} = \varepsilon_l c_{la}\ . \tag{12}$$

Of course, the right-hand sides of these equations should be, in general, of the form of $\sum_k \varepsilon_{lk} c_{ka}$, but the electronic energy is invariant for the orthogonal transformotion between c_{la}'s ($l=1, \cdots, n$; $a=1, 2, \cdots$), we can choose c_{la}'s so that $\varepsilon_{lk}=0$ for $l \neq k$, and the equations above would reduce to a normal eigen-value problem if the c_{la}'s in the bracket would be known.

ii. Closed-shell plus unpaired electrons all with parallel spins

Assume that $2n$ electrons occupy the molecular orbitals $\psi_1, \cdots, \psi_n$ doubly and m electrons occupy the molecular orbitals $\psi_{n+1}, \cdots \psi_{n+m}$ singly all with parallel spins. Pople and others assumed that electrons with different spins occupy two distinct sets of molecular orbitals. We adopt a somewhat different assumption as mentioned above, and take the electronic wave function as follows,

$$\Phi = \frac{1}{\sqrt{(2n+m)!}} \det|\psi_1(1)\alpha(1)\psi_1(2)\beta(2)\cdots\psi_n(2n)\beta(2n)$$

$$\times \psi_{n+1}(2n+1)\alpha(2n+1)\cdots\psi_{n+m}(2n+m)\alpha(2n+m)| \tag{13}$$

The energy integral is

$$\begin{aligned}\mathscr{E}=2\sum_{l=1}^{k}\sum_{a}c_{la}^{*}c_{la}\Big\{-I_a+\frac{1}{4}\sum_{k=1}^{n+m}\sigma_k c_{ka}^{*}c_{ka}(I_a-E_a)-\sum_{b\neq a}\Big(\frac{Z_b e^2}{R_{ab}}-\frac{1}{2}\sum_{k=1}^{n+m}\sigma_k c_{kb}^{*}c_{kb}\frac{e^2}{R_{ab}}\Big)\Big\}\\ +\sum_{l=n+1}^{n+m}\sum_{a}c_{la}^{*}c_{la}\Big\{-I_a+\frac{1}{2}\sum_{k=1}^{n}c_{ka}^{*}c_{ka}(I_a-E_a)-\sum_{b\neq a}\Big(\frac{Z_b e^2}{R_{ab}}-\frac{1}{2}\sum_{k=1}^{n+m}\sigma_k c_{kb}^{*}c_{kb}\frac{e^2}{R_{ab}}\Big)\Big\}\\ +\sum_{l=1}^{n+m}\sum_{a}\sum_{b\neq a}\sigma_l c_{la}^{*}c_{lb}\Big\{\beta_{ab}-\frac{1}{4}\sum_{k=1}^{n+m}\sigma_k c_{kb}^{*}c_{ka}\frac{e^2}{R_{ab}}\Big\}+H_0\,,\end{aligned}$$

where σ is the occupation number. The S.C.F. equations are

$$\begin{aligned}&c_{la}\Big\{-I_a+\frac{1}{2}\sum_{k=1}^{n+m}\sigma_k c_{ka}^{*}c_{ka}(I_a-E_a)-\sum_{b\neq a}\Big(\frac{Z_b e^2}{R_{ab}}-\sum_{k=1}^{n+m}\sigma_k c_{kb}^{*}c_{kb}\frac{e^2}{R_{ab}}\Big)\Big\}\\ &\quad+\sum_{b\neq a}c_{lb}\Big\{\beta_{ab}-\frac{1}{2}\sum_{k=1}^{n+m}\sigma_k c_{kb}^{*}c_{ka}\frac{e^2}{R_{ab}}\Big\}=\varepsilon_l c_{la}+\sum_{k=n+1}^{n+m}\frac{\varepsilon_{lk}}{2}c_{ka}\,,\qquad \text{for}\quad 1\leq l\leq n\,,\\ &c_{la}\Big\{-I_a+\sum_{k=1}^{n}c_{ka}^{*}c_{ka}(I_a-E_a)-\sum_{b\neq a}\Big(\frac{Z_b e^2}{R_{ab}}-\sum_{k=1}^{n+m}\sigma_k c_{kb}^{*}c_{kb}\frac{e^2}{R_{ab}}\Big)\Big\}\\ &\quad+\sum_{b\neq a}c_{la}\Big\{\beta_{ab}-\Big(\sum_{k=1}^{n}c_{kb}^{*}c_{ka}+\sum_{k=n+1}^{n+m}c_{kb}^{*}c_{ka}\Big)\frac{e^2}{R_{ab}}\Big\}=\sum_{k=1}^{n}\varepsilon_{lk}c_{ka}+\varepsilon_l c_{la}\,,\\ &\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{for}\quad n+1\leq l\leq n+m\end{aligned}$$

where $\varepsilon_{lk}^{*}=\varepsilon_{kl}$.

It should be noted that, in this case, $\varepsilon_{lk}\neq 0$ if the occupation numbers of ψ_l and ψ_k are not equal, because we cannot perform the orthogonal transformation between the orbitals with different occupation numbers. As mentioned in the earlier part of this section, we do not attempt to construct the S.C.F. wave functions for individual states, and it is desirable to use for any state the orbitals derived by the S.C.F. equations for the appropriate standard state. If the standard state is of a closed-shell structure, we can define a set of virtual orbitals in addition to real orbitals, because the equations would be linear ones associated with a normal secular equation being independent of l, if the c_{la}'s in the bracket at the left-hand side of Eq. (15) would have been determined, and we can construct the wave functions of the excited or ionized states in terms of these virtual orbitals. Unfortunately, this is not the case if the standard state is not of a closed-shell structure, because the equations are different from orbital to orbital depending on the occupation number and coupling of spin, and we cannot define virtual orbitals uniquely. But, in order to discuss the properties related solely with the ground state, the S.C.F. method is still most convenient even for non closed-shell configulation, and, for the phenomena related also with the excited or ionized states, it may necessary to simplify the calculation so th the method is a one which is capable of d fining virtual orbitals as well as real orbita With respect of this point, Hall[8] proposed idea of the standard excited state, i.e., t state where all the electrons have the sam spin. In this case, the S.C.F. equations ar for an m-electron system,

$$\begin{aligned}&c_{la}\Big\{-I_a-\sum_{b\neq a}\Big(\frac{Z_b e^2}{R_{ab}}-\sum_{k=1}^{m}c_{kb}^{*}c_{kb}\frac{e^2}{R_{ab}}\Big)\Big\}\\ &\quad+\sum_{l\neq a}c_{lb}\Big\{\beta_{ab}-\sum_{k=1}^{m}c_{kb}^{*}c_{ka}\frac{e^2}{R_{ab}}\Big\}=\varepsilon_l c_{la}\,.\end{aligned}$$

These would be a normal eigen-value proble if the c_{la}'s in the bracket would have bee known. Hall's idea is convenient for our pr sent purpose and we shall discuss on t problem in a later part of this series from somewhat different point of view.

In the method used by Pople, there are milar difficulties to those mentioned abov and, in addition, it may be more serious th his wave function is not the correct eige function for the total spin operator.

§ 4. Estimation of Parameters for Hydr carbons

In the present procedure, we intend to timate the integrals β and e^2/R in terms mpirical data for smaller molecules. This an be carried out for carbon-carbon pairs as nown in the following.

For the ethylene molecule, the first singlet nd triplet state energies and the ionization nergy are given by

$$E_S=\frac{1}{2}(I_C-E_C)-\frac{1}{2}\frac{e^2}{R}-2\beta\,, \qquad (18)$$

$$E_T=-\frac{1}{2}(I_C-E_C)+\frac{1}{2}\frac{e^2}{R}-2\beta\,, \qquad (19)$$

$$I=\frac{1}{2}(I_C+E_C)+\frac{1}{2}\frac{e^2}{R}-\beta\,, \qquad (20)$$

espectively, neglecting configuration interacons. In the present approximation, the trilet energy is equal to the π-bond energy. is the ionization potential of the valence ate of the carbon atom and concerned with ^{3}(IV) → sp^2(III) and E_C is the electron affiity concerned with sp^3(IV) → sp^4(III). We nall adop the value 11.54 eV and 0.46 eV for and E_C, respectively, estimated by Skinner nd Pritchard9).

We must determine the values of β and $/R$ as functions of the interatomic distance. he precise dependence of these parameters n the interatomic distance is not very imortant at the present stage of approximation nd we may assume rather crudely that

$$\frac{e^2}{R}=\frac{1-\exp(-\kappa r)}{r}\,. \qquad (21)$$

is a parameter, which is determind by

$$\frac{e^2}{R}(r=0)=I_C-E_C=11.08\,.$$

$$\kappa=0.7645/\text{Å}$$

sing this value of κ, the value of β at $r=$ .34 Å is determined by equations (18), (19) nd (20), so that the calculated E_S, E_T and I gree with experiments as well as possible. he value of $\beta=-2.2016$ eV is found to be ost favorble. The calculated and expeiental values of E_S, E_T and I are shown elow.

	calc.	exptl.
E_S	6.48 eV	7.60 eV$^{10a)}$
E_T	2.30 〃	3.30 〃 $^{10b)}$
I	11.67 〃	10.62 〃 $^{11)}$

Ve assume that the double bond energy is ivided into the part due to the σ-bond and at due to the π-bond; the former attains to s maximum value at $r=1.54$ A, i.e., the C—C distance in the ethane moleculue, and the maximum of the whole double bond energy is at $r=1.34$ A, i.e., the C—C distance in the ethylene molecule. The π-bond energy is, therefore, assuming the parabolic variation of bond energies with $r^{12)}$,

$$E_\pi=E_0-f_d(r-r_d)^2+f_s(r-r_s)^2$$
$$=-\frac{1}{2}(I_C-E_C)+\frac{1}{2}\frac{e^2}{R}-2\beta\,, \qquad (22)$$

where E_0 is a constant, and f_d and f_s are half the stretching force constant for the C=C bond of the ethylene and the C—C bond of the ethane molecule, respectively. From the above, we can determine the value of β as a function or r, using$^{13)}$

$$f_s=14.045\ \text{eV/A}^2\,,$$
$$f_d=29.963\ \text{eV/A}^2\,,$$
$$E_\pi(r=1.34\ \text{A})=2.30\ \text{eV}\,.$$

The calculated values of β are shown in the Table below as a function of r.

Table I. Value of β as a function of r.

r	$-\beta$
1.34 A	2.2016 eV
1.35	2.1781
1.36	2.1533
1.37	2.1267
1.38	2.0984
1.39	2.0687
1.40	2.0373
1.41	2.0042
1.42	1.9694
1.43	1.9331
1.44	1.8951
1.45	1.8556
1.46	1.8144
1.47	1.7716
1.48	1.7272
1.49	1.6810
1.50	1.6385
1.51	1.5843
1.52	1.5335
1.53	1.4812
1.54	1.4271

If the configuration interaction can be neglected as above, the concept of bond order is useful for the closed-shell structures, and, if assuming that the bond distance is determined by the bond order of the bond concerned, irrelevant to the remaining part of the molecule, when the steric condition is favorable, it is useful to set down the relation between the π-bond order and the double bond length. The π-bond order p has been defined by

$$p_{ab}=\frac{1}{2}\sum_{l}\sigma_l(c_{lb}{}^*c_{la}+c_{lb}c_{la}{}^*)$$

and, for the closed-shell structure, the part of the total energy due to the bond $a-b$ is

$$E_{ab}=E_s+p_{ab}\left\{2\beta-\frac{p_{ab}}{2}\frac{e^2}{R}\right\} \tag{23}$$

except for the effects of the formal charge and the steric hindrance. E_s is the σ-bond energy which is given by

$$E_s=E_{so}+f_s(r-r_s)^2\ . \tag{24}$$

If the state is not of the closed-shell structure, E_{ab} is not given by equation (23). The interatomic distance is determined by the minimization of E_{ab} with respect to r for a given p, and p, in turn, is determined by the electronic wave function and, hence, by r through the parameters β and e^2/R. Thus, the wave function should be self-consistent for the variation of r, as well as it should be so for equation (23). The relation between p and r is shown in the figure.

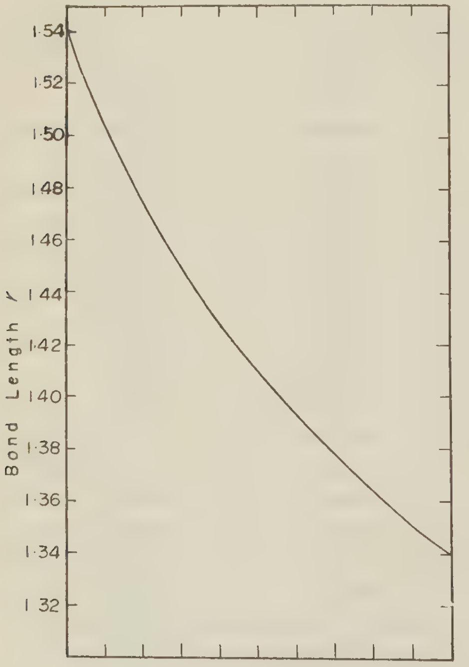

Fig. 1.

§ 5. Some Simple Application to Hydrocarbons

Though the electronic structures of simple alternant hydrocarbonmolecules have been discussed by many investigators, using both semi-empirical and non-empirical method, and their spectra have been explained systematically14), we shall illustrate some typical applications to those molecules in order to show that our method gives quite reasonable result in spite of its simplicity.

It should be noted that, in the previously proposed molecular orbital theories which do or do not include the electronic interaction in the semi-empilical scheme, the parameter β, remains an adjustable constant so as to agree the calculated results with the experiments for the individual cases. It has been thus pointed out that, in order to predict the positions of the energy levels of the linear and the condensed alternant hydrocarbons, we must use different values of β, or, in order to predict the values of the resonance energy and the excitation energies of a hydrocarbon molecule, we cannot do with one value of β15). Our present method gives the way how to determine the value of β for individual bonds as a function of the interatomic distance of the bond, which we can calculate self-consistently, if desired.

In the Table below, we show the results of the calculation for the butadiene and the benzene molecules. For alternant hydrocarbons Hueckel orbitals are self-consistent except the use of the same resonance integral for all the bonds, instead of $\beta-\frac{p}{2}\frac{e^2}{R}$ which are to be different for different bonds in the present approximation, and we have used here Hueckel orbitals instead of the true S.C.F. orbitals for the butadiene molecule. Moreover, we have considered only the configuration interaction between states that have the same energy in the simple Hueckel theory, which Moffitt called the first order configuration interaction. The agreement between the calculated and the observed results is found to be satisfactory.

A Semi-empirical Theory of the Conjugated Systems

II. Bond Alternation in Conjugated Chains

By Yuzuru OOSHIKA

Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received July 23, 1957)

The problem of the convergence of the absorption wave-lengths of chain conjugated systems, polyenes, and merocyanines, is discussed, by using the method developed in the previous paper. It is shown that the bond alternation as the cause of the convergence of the absorption wave-lengths, which has been presumed from the view of the resonance theory but cannot be deduced in terms of the ordinary molecular orbital theory, do actually occurs even for an infinite polyene chain, but the calculated limiting wavelength does not agree with the experiment quantitatively, possibly because of the coulomb attraction between the excited electron and the hole.

§1. Introduction

The explanation of the low energy transitions of chain conjugated molecules have long been a subject of many theoretical papers since Herzfeld and Sklar[1] first discussed such molecules in detail on the basis of both the molecular orbital and the resonance method. The most remarkable experimental fact is that, though wave-lengths of absorption maxima of certain types of molecules, e.g., symmetrical cyanines, increase linearly about by 1000 A for every vinylene group in the chain, those of other types of molecules, e.g. unsymmetrical cyanines, merocyanines, and polyenes, deviate more and more towards shorter wave-lengths from those of symmetrical cyanines as the lengths of the chains become larger and larger, and seem to converge to certain limiting wave-lengths. On the details of the experimental results, the reader can refer to many papers referred by J. R. Platt,[2] especially to a series of works by L. G. S. Brooker.

Attempts have been proposed by many investigators to explain the deviations and the convergence of the absorption wave-lengths of the so-called convergent dyes (or molecules). Herzfeld and Sklar[1] showed that, on the basis of the resonance theory, the energy of the first transition converges to a finite value as the length of the chain becomes infinitely large, if the energies of the two lowest extreme resonance structures are different, but that, if we use the ordinary molecular orbital method, the transition energy of the unsymmetrical dye approaches to zero as well as that of the symmetrical dye, though the former deviates from the latter. On the other hand, Kuhn,[3] using the free electron model, showed that, if the potential for the electrons is not uniform but has maxima and minima at the alternate carbon atoms, respectively, the transition energy approaches a finite value with increasing chain length. The polyenes have only one lowest resonance structure, and it may be reasonable to suppose that the potential is of such a form that Kuhn assumed from the point of view of the resonance theory, because of the bond alternation in the lowest resonance structure. The situation is similar in unsymmetrical cyanines and merocyanines. But, from the point of view of the molecular orbital theory, it is not obvious whether the effect Kuhn supposed remains for an infinitely long chain, since the effect is to be considered only an end effect.

From the entirely different point of view, Araki and others,[4] applying the theory of the plasma oscillation, showed that the deviation and the convergence of the absorption wave-length can be successfully explained by taking into account the electronic interaction, which is of primary importance for large systems. Though the predictions of the absorption by their method can be brought into very good agreement with the experiments by using only one parameter for very large number of molecules, and though the electronic interaction is undoubtedly of importance as they suggested, the value of the parameter cannot be considered physically reasonable, and, further, the reason why the absorption wave-lengths of some homologues seem to increase linearly with increasing chain length, while those of others seem to be strongly convergent is not clear.

Recently, Platt[2] published a paper, in which he discussed the problem of the absorption spectra of the conjugated chain molecules in detail, and gave a way how to predict the absorption wave-length for any molecule semi-empirically. He postulated the importance of the "configuration interaction," as he called, and stated that the configuration interaction causes the bond alternation and, hence, the potential is of such a form as Kuhn supposed, and thus the absorption wave-length converges. But he did not formulate actually how the configuration interaction causes the bond alternation.

From all the experimental and theoretical facts mentioned above, it may be almost without doubt that the electronic interaction and the bond alternation resulting from it are the cause of the convergence of the absorption wave-lengths of the convergent molecules. But, if we stand on the basis of the previously proposed treatment in terms of the ordinary molecular orbital theory, even if the bonds near the ends of the chain have single and double bond characters alternately, it is shown that the degree of the alternation becomes smaller and smaller as we go towards the center of the chain, and that, for an infinite chain, the bond alternation gives only an infinitesimal effect on the energy levels and the wave functions.

The purpose of the present paper is to show that the bond alternation can actually exist for an infinite polyene chain by means of the semi-empirical molecular orbital method developed in the preceding paper, and to predict the absorption spectra of the polyene chains.

§ 2. Bond Alternation in Conjugated Hydrocarbon Chains

Consider a polyene molecule composed of $2n$ carbon atoms. If we assume that the interaction integral $\gamma\left(=\beta-\dfrac{p}{2}\dfrac{e^2}{R}\right.$ in our preceding notation) between neighboring carbon atoms is independent upon the position of the bond, and that the other interactions are negligible, the molecular orbitals (Hueckel orbitals) are

$$\psi_l=\sqrt{\frac{2}{2n+1}}\sum_{s=1}^{2n}\sin\frac{ls\pi}{2n+1}\phi_s\,, \tag{1}$$

where ϕ_s's are the normalized $2p\pi$—atomic orbitals, and the orbital energies are

$$\varepsilon_l=\alpha+2\cos\frac{l\pi}{2n+1}\gamma\,. \tag{2}$$

The firist singlet excitation energy is, therefore,

$$\left.\begin{aligned}E(n,n+1)=&-\frac{2}{2n+1}\left(\cos\frac{n+1}{2n+1}\pi-\cos\frac{n}{2n+1}\pi\right)\gamma\\&+\frac{4}{(2n+1)^2}\left\{\sum_s\sin^2\frac{(n+1)s}{2n+1}\pi\sin^2\frac{ns}{2n+1}\pi(I_c-E_c)\right.\\&-\sum_s\sum_{t\neq s}\sin^2\frac{(n+1)s}{2n+1}\pi\sin^2\frac{ns}{2n+1}\pi\cdot\frac{e^2}{R_{st}}\\&\left.+2\sum_s\sum_{t\neq s}\sin\frac{ns}{2n+1}\pi\sin\frac{nt}{2n+1}\pi\sin\frac{(n+1)s}{2n+1}\pi\sin\frac{(n+1)t}{2n+1}\cdot\frac{e^2}{R_{st}}\right\}\end{aligned}\right\} \tag{3}$$

The bond order between the s-th and the t-th carbon atom is

$$P_{st}=\frac{1}{2n+1}\left\{\frac{\sin(s-t)\pi/2}{\sin\dfrac{(s-t)\pi}{2(2n+1)}}-\frac{\sin(s+t)\pi/2}{\sin\dfrac{(s+t)\pi}{2(2n+1)}}\right\} \tag{4}$$

These Hueckel orbitals are, of course, not self-consistent, because of the difference of bond orders for different bonds. But, for an infinitely long polyene chain, the bond order between the s-th and the $s+1$-th atom is

$$\begin{aligned}P_{s,\,s+1}=&\lim_{n\to\infty}\frac{1}{2n+1}\left\{\frac{1}{\sin\pi/2(2n+1)}-\frac{\sin(s+1/2)\pi}{\sin((s+1/2)\pi/(2n+1))}\right\}\\=&\,2/\pi-(-1)^s2/(2s+1)\pi\,.\end{aligned}$$

Thus, the bond alternation occurs near the chain ends, but it is damped as s increases till the bond order becomes $\pi/2$ for bonds far from the ends. The Hueckel orbitals are, therefore, self-consistent for an infinitely long chain except for the bond alternation near the ends of the chain, and, as the end effect may be neglected for a long chain, the results obtained by using the Hueckel orbitals may be correct for a long chain. (The Hueckl orbitals are actually Bloch orbitals for an infinite chain.) Hence, it is shown that the first excitation energy $E(n, n+1)$ tends to zero with $n \to \infty$ from equation (3).

Thus, it is impossible to show by such an ordinary method that the bond alternation still remains for an infinitely long chain and that the wave-length does not increase linearly with the chain length but converges to a certain definite limit. But the self-consistency of the Hueckel orbitals does not mean the minimum of the total energy with respect to any variation of the parameters, but means only the stationary value of the energy, and if we allow the alternate increase and decrease of the interaction integrals between neighboring atomic orbitals, it may be quite possible that the minimum of the energy is at the point where the two interaction integrals mentioned above are different from each other and that the bond alternation occurs actually also near the center of the chain.

Now, for an infinite system, we shall obtain the same result, no matter whether we treat an open chain, or we connect the two end atoms and make a closed ring. So we carry out the calculation for a $2n$-membered ring and consider the limit $n \to \infty$ for the sake of simplicity of the boundary condition. Number the atoms as $1, 2, 3, \cdots, 2n$, and denote $-\gamma_1$ by the interaction intgral for bonds between the $2s-1$-th and the $2s$-th atom and by $-\gamma_2$ that for bonds between the $2s$-th and the $2s+1$-th atom, including the bond between the $2n$-th and the first atoms. γ_1 and γ_2 are assumed to be independent on s, and the interactions between non-neighbors are assumed to be negligible. The latter assumption does not influence the form of the molecular orbitals for a closed ring. The molecular orbitals are expressed as follows,

$$\begin{aligned} \psi_l^1 &= x\psi_{l0} + x'\psi_{le} , \\ \psi_l^2 &= x'\psi_{l0} - x\psi_{le} , \end{aligned} \qquad l=0, 1, 2, \cdots, n-1 \qquad (6)$$

$$\begin{aligned} \psi_{l0} &= \frac{1}{\sqrt{n}} \sum_{s=1}^{n} e^{ik(2s-2)}\psi_{2s-1} , \\ \psi_{le} &= \frac{1}{\sqrt{n}} \sum_{s=1}^{n} e^{ik(2s-1)}\psi_{2s} , \end{aligned} \qquad k=\frac{\pi}{n} l \qquad (7$$

$$\begin{aligned} (\alpha-\mathcal{E})x-(\gamma_1 e^{ik}+\gamma_2 e^{-ik})x' &= 0 , \\ -(\gamma_1 e^{-ik}+\gamma_2 e^{ik})x+(\alpha-\mathcal{E})x' &= 0 , \end{aligned} \qquad (8$$

where $\mathcal{E}$ is the orbital energy. Solving the equations (8) and considering the normalization we obtain

$$x=\frac{1}{\sqrt{2}}e^{i\theta} , \qquad x'=\frac{1}{\sqrt{2}}e^{-i\theta} , \qquad (9$$

$$\tan 2\theta = \frac{\gamma_1-\gamma_2}{\gamma_1+\gamma_2} \tan k , \qquad \pi > 2\theta \geq 0 , \qquad (10$$

$$\alpha-\mathcal{E} = \pm\sqrt{\gamma_1{}^2+\gamma_2{}^2+2\gamma_1\gamma_2 \cos 2k} , \qquad (1$$

Here, we assumed $\gamma_1 \geq \gamma_2 > 0$, and, hence, the plus and minus signs in the equation (11) correspond to $\psi_l{}^1$, $\psi_l{}^2$, respectively. Thus, we can see that the one electron energy levels are split into two bands, as expected, one the bonding and the other the antibonding. Now we shall determine γ_1 and γ_2 by means of the method in the preceding paper, and shall show that the bond alternation remains for an infinite chain.

The partial π-bond order of the $2s-1$—$2s$ bond ("double bond") and the $2s$—$2s+1$ bond ("single bond") due to the bonding orbital k are

$$\left.\begin{aligned} p_d(k) &= \frac{1}{n}(x^*x'e^{ik}+xx'^*e^{-ik}) \\ &= \frac{\gamma_1+\gamma_2 \cos 2k}{n\sqrt{\gamma_1{}^2+\gamma_2{}^2+2\gamma_1\gamma_2 \cos 2k}} , \\ p_s(k) &= \frac{1}{n}(x^*x'e^{-ik}+xx'^*e^{ik}) \\ &= \frac{\gamma_2+\gamma_1 \cos 2k}{n\sqrt{\gamma_1{}^2+\gamma_2{}^2+2\gamma_1\gamma_2 \cos 2k}} , \end{aligned}\right\} \qquad (12)$$

respectively. Thus, for an infinitely large ring, the bond order of the "double" and the "single" bond are

$$\left.\begin{aligned} P_d &= \lim_{n\to\infty} \sum_{\text{bonding}} p_d(k) \\ &= \frac{1+z}{\pi}E\left(\frac{2\sqrt{z}}{1+z}\right)+\frac{1-z}{\pi}K\left(\frac{2\sqrt{z}}{1+z}\right) \end{aligned}\right\} \qquad (13)$$

$$\left.\begin{aligned} P_s &= \lim_{n\to\infty} \sum_{\text{bonding}} p_s(k) \\ &= \frac{1+z}{z\pi}E\left(\frac{2\sqrt{z}}{1+z}\right)-\frac{1-z}{z\pi}K\left(\frac{2\sqrt{z}}{1+z}\right) \end{aligned}\right\} \qquad (14)$$

where $z=\gamma_2/\gamma_1$ and K and E are the perfect elliptic integrals of the first and the second kind, respectively.

From these equations for P_d and P_s, and he relation between the bond order and the nteraction integral $\beta-\frac{p}{2}\frac{e^2}{R}$, we can determine the bond orders, bond lengths, and the values of $\beta-\frac{p}{2}\frac{e^2}{R}$ self-consistently. The results are shown below.

	$z=1$	$z=0.484$ "double bond"	"single bond"
P	$2/\pi$	0.938	0.249
r	1.389 A	1.346 A	1.463 A
γ	4.244 eV	5.437 eV	2.632 eV

The solution $z=1$ corresponds to an ordinary cyclic polyene, and it is easily seen by calculating the adiabatic resonance energy from the values of γ_1 and γ_2 above that $z=0.484$ corresponds to the lower energy. The calculation of the adiabatic resonance energy for $z=1$ and $z=0.484$ is shown below.

total π-electron energy	double bond	single bond
(per two electrons)	−8.040 eV	−8.262 eV
vertical resonance energy (〃)	0.484	0.427
bond compressional energy (〃)	0.392	0.084
adiabatic resonance energy (〃)	0.092	0.343

Thus, we see that the bond alternation lowers the total energy.

In the calculation above, we neglected the effects of the interactions between non-neighboring atoms, but, for benzene, they contribute only 10 % to the resonance energy, and it is not probable that they influence the conclusion reached above.

Our calculation concerns with an infinitely large conjugated ring, the result of which is also applicable to an infinitely long polyene, and, if a position of a "double" and "single" bond is determined at any part of the molecule, its influence extends to the whole molecule. For an infinitely long chain, the bond alternation is to occur at the ends as short—long—short—long— as shown in the earlier part of this section, and the whole bond alternation is determined by the ends of the molecule, i.e., the atoms do know how far they are from the end.

As one-electron energy levels are slipt into two bands as shown above, it is expected that the absorption wave-length does not tend to infinity with increasing chain length. The singlet transition energy is

$$E(n,n+1)=I-E$$
$$-\int\phi_n^*(1)\phi_{n+1}^*(2)\frac{e^2}{r}\phi_n(1)\phi_{n+1}(2)d\tau$$
$$+2\int\phi_n^*(1)\phi_{n+1}^*(2)\frac{e^2}{r}\phi_{n+1}(1)\phi_n(2)d\tau$$

and the calculated limit of the absorption energy equals to the gap between the bands, because the last two terms in the right-hand side of the above equation tend to zero for an infinite system. But, for such an infinite system, it cannot be expected that the excitation energy is correctly calculated by the method above, because of the neglect of the attraction between the hole and the electron. In fact, the energy gap between the filled and the vacant band is 5.6 eV, and the experimental limiting excitation has been estimated to be about 2.5 eV2) i.e., about half the calculated value.

§ 3. Discussion

The conclusion above is to be applied to all chain molecules, and the limiting absorption wave-length of any such molecule is to tend to the same finite value, because the bond alternation is a "bulk" effect and not a "surface" effect. But, actually, the absorption wave-lengths of symmetrical cyanines seem to tend to infinity, while those of unsymmetrical cyanines and merocyanines seem to tend to individual values. Here, we must remember that the experiments on various homologous series which led to the above conclusion have been carried out for molecules with at most about 10 carbon-carbon bonds, and, in such cases, our conclusions for an infinite system are not applied as such. As shown by the resonance theory, it is no wonder that, for cyanines with conjugated systems with odd numbers of atoms, symmetrical ones do not show any convergence of the absorption wave-lengths and the deviations of unsymmetrical ones are different from molecule to molecule for conjugated chains not sufficiently long.

The treatment in the previous section is to be applied to smaller systems, and it may be interesting to examine whether the benzene molecule would be of the configuration with the bond alternation. We shall show that this is not the case, and that the bond alternation does not occur in the benzene molecule. For $n=3$, the total π-bond orders of the "double" and the "single" bond are

$$P_d=\frac{1}{3}+\frac{2-z}{3\sqrt{1-z+z^2}}$$

$$P_s=\frac{1}{3}+\frac{2z-1}{3\sqrt{1-z+z^2}}\,,$$

respectively. By the method similar to that in the previous section, we can obtain the self-consistent solution, but, in this case, $z=1$ is the only solution and, hence the benzene molecule has the hexagonal symmetry.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 11, NOVEMBER, 1957

The Lower Excited States and the Phosphorescent State of Diphenyl I.

By Kaoru IGUCHI

Centre de Chimie Théorique de France

(Received July 10, 1957)

We have calculated the lower excited π electronic states of diphenyl, employing Pariser approximation and assuming empirical values for the atomic Coulomb integrals: $(11|11)=10.959$ ev, $(11|22)=6.895$ ev, $(44|55)=6.546$ ev. We have obtained B_{3u} state for the lowest excited singlet, against the B_{2u} state obtained by London where the products of wave functions for benzene molecule were utilized. A method to treat the phenomena of phosphorescence has been suggested and the group theoretical classification of combination by L–S interaction is discussed.

§ 1. Introduction

The electronic energy levels of polyacene have been calculated and discussed by many authors[1)-7)], but the polyphenyl molecules are not yet treated so much. The π electronic energy levels of diphenyl were calculated by London[1)] by utilizing, as an approximation, the product of wave functions computed for benzene molecule by Goeppert-Mayer and Sklar[9)]. The method of London, however, does not take account enough of the ionic structures which seem to be important in view of the remarkable properties of fluorescene and phosphorescence of this molecule[8)]. In this article, the lower excited levels of diphenyl have been calculated by the molecular orbital method, constructing the linear combination of atomic π orbitals for all the molecule, employing the approximation proposed by Pariser. This method will probably overestimate the importance of the ionic structures such as;

However, a certain number of recent publications have shown that the relative weight of these structures is great even in the ground state when the configuration interaction is taken into account[10)]. We have obtained the results which are a little different from those of London. Probably the actual situation might be between the two types of approximation.

§ 2. Calculation

The geometric structure of the molecule and the axes of coordinates are assumed as hown in Fig. 1. The molecule has the symnetry of V_h and each symmetry orbital beongs to one of the irreducible representations B_{1u}, B_{2g}, B_{3g} and A_{1u} as shown in the Table I.

Table I. Symmetry orbitals

$$B_{1u}:\ \frac{1}{\sqrt{2}}(\chi_1+\chi_8)\,,\quad \frac{1}{\sqrt{2}}(\chi_4+\chi_5)\,,\quad \frac{1}{2}(\chi_2+\chi_{2'}+\chi_7+\chi_{7'})\,,\quad \frac{1}{2}(\chi_3+\chi_{3'}+\chi_6+\chi_{6'})$$

$$B_{2g}:\ \frac{1}{\sqrt{2}}(\chi_1-\chi_8)\,,\quad \frac{1}{\sqrt{2}}(\chi_4-\chi_5)\,,\quad \frac{1}{2}(\chi_2+\chi_{2'}-\chi_7-\chi_{7'})\,,\quad \frac{1}{2}(\chi_3+\chi_{3'}-\chi_6-\chi_{6'})$$

$$B_{3g}:\ \frac{1}{2}(\chi_2-\chi_{2'}+\chi_7-\chi_{7'})\,,\quad \frac{1}{2}(\chi_3-\chi_{3'}+\chi_6-\chi_{6'})$$

$$A_{1u}:\ \frac{1}{2}(\chi_2-\chi_{2'}-\chi_7+\chi_{7'})\,,\quad \frac{1}{2}(\chi_3-\chi_{3'}-\chi_6+\chi_{6'})$$

One can express the symmetry orbital S_l of symmetry Γ in the form:

$$S_l=\sum_A \sigma_A{}^l(\Gamma')\chi_A\,,\quad \Gamma=\Gamma'\times B_{1u}\,, \tag{1}$$

where A numerates the nuclei, and χ_A is the $2p\pi$ atomic orbital of Slater type centred on A and we have taken $Z=3.18$.

In every subspace corresponding to an irreducible representation, we have solved the secular equation of Hückel[11] which gives the energy of each orbital in the form;

$$E=E^0-\alpha+\rho\beta\,. \tag{2}$$

The value of ρ obtained are given in the Table II[12].

Table II. Values of ρ

B_{1u}	B_{2g}	B_{3g}	A_{1u}
$\rho_{2'}$ 1.8909	$\rho_{1'}$ 2.2791	$\rho_{4'}$ 1.0000	$\rho_{5'}$ 1.0000
$\rho_{6'}$ 0.7049	$\rho_{3'}$ 1.3167	ρ_5 −1.0000	ρ_4 −1.0000
ρ_3 −1.3167	ρ_6 −0.7049		
ρ_1 −2.2791	ρ_2 −1.8909		

For every value of ρ, the corresponding molecular orbital of Hückel is constructed in the form of linear combination of symmetry orbitals given in Table I.

With these MO's (molecular orbitals) ϕ_i, we construct the antisymmetrized wave functions for all the molecule as;

$$\left.\begin{array}{ll} \text{ground state} & V_0=|1\bar{1},\,2\bar{2},\,\cdots,\,6\bar{6}|\,, \\ \text{excited states} & \left\{\begin{array}{l} \text{singlets}\ \ V_{ik'}=\dfrac{1}{\sqrt{2}}\{|1\bar{1},\,\cdots,\,i\bar{k}',\cdots,\,6\bar{6}|-|1\bar{1},\,\cdots,\,\bar{i}k',\,\cdots,\,6\bar{6}|\} \\ \text{triplets}\ \ T_{ik'}=\dfrac{1}{\sqrt{2}}\{(1\bar{1},\,\cdots,\,i\bar{k}',\cdots,\,6\bar{6}|+|1\bar{1},\,\cdots,\,\bar{i}k',\,\cdots,\,6\bar{6}|\} \end{array}\right. \end{array}\right\} \tag{3}$$

Here the number without bar means a MO with α spin, and that with bar a MO with β spin.

For the consequence, the lower energy levels of the molecule are, in the Hückel approximation, as follows:

1st $\cdots$ $V_{66'}$, $T_{66'}(B_{3u})$,
2nd $\cdots$ $V_{56'}=V_{65'}$, $T_{56'}=T_{65'}(B_{2u})$, $V_{46'}=V_{64'}$, $T_{46'}=T_{64'}B(_{1g})$,

3rd ··· $V_{55'}$, $V_{44'}$, $T_{55'}$, $T_{44'}(B_{3u})$, $V_{54'}=V_{45'}$, $T_{54'}=T_{45'}(A_{1g})$,
4th ··· $V_{63'}=V_{36'}$, $T_{63'}=T_{36'}(A_{1g})$,
etc. ···

By our approximation the wave functions of molecule are represented as linear combinations of the lower mono-excited functions belonging to the same irreducible representation of the symmetry group of the molecule, for example,

$$\psi_a=A_1V_1+A_2V_2+\cdots \qquad (4$$

The energy E_a and the coefficients A_i are given by the solution of a system of secular equations,

$$\sum_n A_n\{H_{mn}-\delta_{mn}E\}=0\,. \qquad (5$$

In the present case, the elements H_{mn} are denoted for the singlet states

$$H_{mn}=\int V_m H V_n dv=\{V_m|V_n\}\,,$$

and for triplet states

$$H_{mn}=\int T_m H T_n dv=\{T_m|T_n\}\,,$$

with

$$H=H^{\text{core}}+\sum_{p<q}1/r_{pq} \text{ in atomic units.} \qquad (6)$$

However[7],

$$\left.\begin{aligned}
&\begin{matrix}\{V_{ik'}|V_{ik'}\}\\ \{T_{ik'}|T_{ik'}\}\end{matrix}-\{V_0|V_0\}=I_{k'k'}-I_{ii}+[ii|k'k']+[ik'|ik']-[ii|ii]-\sum_{f\neq i}\{2[ff|ii]\\
&\qquad\qquad\qquad -2[ff|k'k']-[fi|fi]+[fk'|fk']\}\,,\\
&\{V_{ik'}|V_{jl'}\}=2[ik'|jl']-[ij|k'l']\,,\\
&\{T_{ik'}|T_{jl'}\}=-[ij|k'l']\,,\qquad \text{etc.},\\
&\text{with}\\
&[ij|kl]=\int\phi_i(1)\,\phi_j(1)\frac{1}{r_{12}}\phi_k(2)\phi_l(2)dv_{12}\,,\\
&I_{ii}=\int\phi_i H^{\text{core}}\phi_i dv\,.
\end{aligned}\right\} \qquad (7)$$

For β, the empirical value 2.371 ev proposed by Pariser[7] has been utilized.

These integrals are given as linear combinations of the integrals over the atomic orbitals. In the Pariser approximation the atomic exchange and hybrid integrals are all negleted. For the atomic Coulomb integrals, we have utilized the formulas by Roothaan[13] except for the large interatomic distance where the approximate formula by Pariser[7] (Eq. 75) has been utilized. On the other hand, when the atoms are very near, the semi-empirical values are adopted for the Coulomb integrals, because the atomic orbital of Slater type can not give good values for the small distance. The semi-empirical values employed are as following;

$$\left.\begin{aligned}
&(11|11)=10.959 \text{ ev}\,,\\
&(11|22)=\ \ 6.895 \quad\ ,\\
&(44|55)=\ \ 6.546 \quad\ ,\\
&\text{where}\\
&(pp|qq)=\int\chi_p(1)\,\chi_p(1)\frac{1}{r_{12}}\chi_q(2)\chi_q(2)dv_{12}\,.
\end{aligned}\right\} \qquad (8)$$

The penetration integrals have been calculated by the method of Parr and Crawford[14]. The results of calculation are shown in Table III. Fig. 3 compares the results with those of London.

	${}^3\psi_3 = -0.7615\,{}^3\psi_{44}^+ + 0.6466\,{}_3\psi_{55}^+ + 0.0477\,{}^3\psi_{66}^+$	7.192

$$ {}^1\psi_{ik}^{\pm} = \frac{1}{2}(V_{ik'} \pm V_{ik'})\,, \quad {}^3\psi_{ik'}^{\pm} = \frac{1}{2}(T_{ik'} \pm T_{ki'})\,. $$

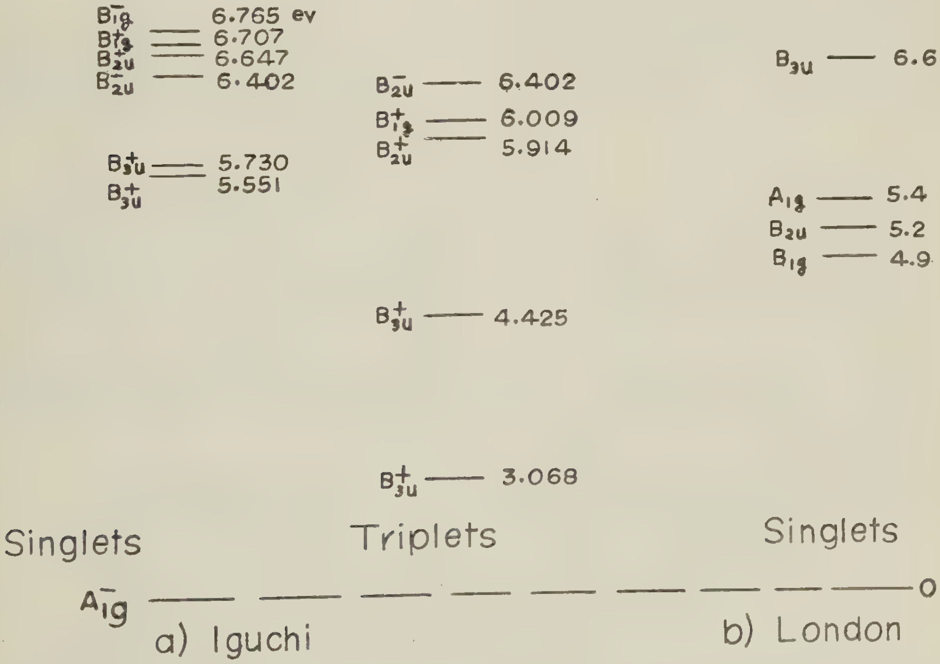

Fig. 3. Energy levels

§ 3. Discussion on the Absorption Spectra

We see that among all the lower excited singlet states B_{3u} state comes to the lowest in our scheme, whereas in the calculation by London B_{2u} comes to the lowest (B_{1g} is neglected because of its optical inactivity). This is the natural result of Hückel approximation. The accordance with the experimental values of absorption spectra is reasonable in both calculations. At present we have no experimental data sufficient to determine the symmetry of the lowest excited singlet state. When higher excited states are taken into account in the configuration interaction, the order of upper states might be changed a little.

§ 4. Treatment of the Phosphorescent State

The phenomenon of the phosphorescence has been studied by many authors[15]. Lewis and Kasha[16] have discussed thoroughly these problems and demonstrated that the phosphorescent level of a molecule is unique, that is, the lowest triplet state. At the low temperature, the lowest triplet state has no vibrational motion, and the fine structure of phosphorescence spectrum shows nothing but the vibrational motions of the ground state.

But the quantitative evaluation of the intensity of the phosphorescence spectrum or the lifetime of the phosphorescent state is difficult, because the matrix elements of the dipole transition are very sensitive to the form of wave functions.

Mizushima and Koide[17] have shown a theoretical method to treat these problems utilizing the theory of group. According to them, the L–S interaction term of a molecule is given, for the jth electron, by:

$$\begin{aligned} H_{LS}(j) &= -\frac{\hbar}{(2mc)^2}\boldsymbol{\sigma}(\mathrm{grad}\ V\times\boldsymbol{p})_j \\ &= \frac{i\hbar^2}{8m^2c^2}\left[2\sigma_z\left(\frac{\partial V}{\partial x}\frac{\partial}{\partial y}-\frac{\partial V}{\partial y}\frac{\partial}{\partial x}\right)\right. \\ &\quad +\frac{\sigma^+ + \sigma^-}{2}\left(\frac{\partial V}{\partial y}\frac{\partial}{\partial z}-\frac{\partial V}{\partial z}\frac{\partial}{\partial y}\right) \\ &\quad \left.+\frac{\sigma^+ - \sigma^-}{2i}\left(\frac{\partial V}{\partial z}\frac{\partial}{\partial x}-\frac{\partial V}{\partial x}\frac{\partial}{\partial z}\right)\right]_j . \end{aligned} \tag{9}$$

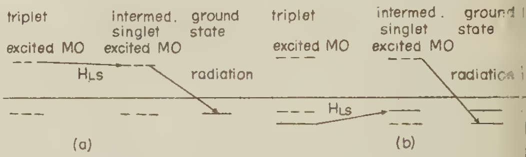
For the V_h symmetry, this is written as

$$H_{LS}(j)=\sigma_z B_{1g}+\frac{\sigma^+ + \sigma^-}{2}B_{3g}+\frac{\sigma^+ - \sigma^-}{2i}B_{2g}\ , \tag{10}$$

where $\boldsymbol{\sigma}$ is the spin operator and V is th
potential.

By the H_{LS} term, the triplet states mix wit
the singlet states (intermediate states), an
the dipole transition can take place from thes
intermediate states to the ground state. Ther
are two processes of intercombination:

a) The electron in the excited MO of th
triplet state is transferred, by the H_{LS} term
to the excited MO of the singlet state, an
then drops into the MO of the ground stat
by the dipole radiation. (Fig. 4a)



--- show the singly occupied orbital
—— show the doubly occupied orbital

Fig. 4. Scheme of intercombination.

b) An electron in the lower MO of the tripl
state is transferred, by the H_{LS} term, t
the MO of the singlet state which was eve
singly occupied, and then the electron in th
excited MO drops into the MO of the groun
state. (Fig. 4b)

The theory of group shows that only th
B_{1g} term of H_{LS} is effective for the intercom
bination and the result is given in Table IV
The state T_{44} does not participate in th
intercombination.

Now the problem of intercombination
reduced to the evaluation of the followin
integral between two combining MO's ϕ ar
ψ;

$$\int V\left(\frac{\partial\phi}{\partial x}\frac{\partial\psi}{\partial y}-\frac{\partial\phi}{\partial y}\frac{\partial\psi}{\partial x}\right)dv\ . \qquad (1$$

Table IV. Scheme of intercombination

	a				b			
Triplet state	$T_{55'}(B_{3u})$	$T_{65'}(B_{3u})$	$T_{56'}(B_{2u})$	$T_{66'}(B_{3u})$	$T_{55'}(B_{3u})$	$T_{56'}(B_{2u})$	$T_{65'}(B_{2u})$	$T_{66'}(B_{3u}$
MO of the triplet state	$\phi_{5'}(A_{1u})$		$\phi_{6'}(B_{1u})$		$\phi_{5'}(A_{1u})$	$\phi_{6'}(B_{1u})$	$\phi_{5'}(A_{1u})$	$\phi_{6'}(B_{1u})$
MO of the intermed. sing. state	$\phi_{6'}(B_{1u})$		$\phi_{5'}(A_{1u})$		occupied: ϕ_5 doubly ϕ_6 singly		ϕ_6 doubly ϕ_5 singly	
Intermed. sing. state	$V_{56'}(B_{2u})$	$V_{66'}(B_{2u})$	$V_{55'}(B_{3u})$	$V_{65'}(B_{2u})$	$V_{65'}(B_{2u})$	$V_{66'}(B_{3u})$	$V_{55'}(B_{3u})$	$V_{56'}(B_{2u}$

f one takes for ϕ and ψ the ordinary linear ombinations of $2p\pi$ atomic orbital and reduces he integral to the sum of integrals between $p\pi$ atomic orbitals, the integrals always anish because of the symmetry property. Mizushima and Koide have avoided this difficulty by including the σ orbitals (though the enzene molecule they have treated has the ymmetry of D_{6h}). But we suppose the problem might be solved even in the domain of orbitals only. For this surpose some modiications of MO are necessary and we are now roceeding on the calculation of modification f MO by the perturbation method, and the esult will be published later.

Acknowledgement

The author wishes to express his sincere hanks to Prof. R. Daudel, Dr. R. Lefebvre of entre de Chimie Théorique de France, and qually to Prof. M. Kotani of the University f Tokyo for their very kind and useful dvice.

Paramagnetic Resonance in Copper Acetate Monohydrate

By Hidetaro ABE* and Junji SHIMADA

Institute of Science and Technology, University of Tokyo, Tokyo

(Received August 1, 1957)

At four microwave frequency bands (λ=78, 10, 16 and 32 mm), single crystals of copper acetate monohydrate, $Cu(CH_3COO)_2H_2O$, were examined at room temperature by the method of paramagnetic resonance absorption, the results differing somewhat from those of usual copper salts. They can be explained by a spin-Hamiltonian with an effective spin $S=1$ which is considered to be originated from a pair of Cu^{++} ions each in ^2D state, holding a strong interaction between them. This is consistent with the results of X-ray crystallography; this crystal consists of bimolecular units $Cu_2(CH_3COO)_4 \cdot 2H_2O$, in which two copper ions approach as close as 2.64 Å. Exchange energy between these copper ions in the unit was estimated using the parameters determined from the resonance spectra and its temperature dependence is discussed.

1. Introduction

When usual hydrated copper salts are examined by the method of paramagnetic resonance absorption, there appears one resonance peak at the value of applied static field H given by

---

* Member of Physics Department, Ochanomizu niversity, Tokyo.

$$h\nu = g\beta H \qquad (1)$$

where h is the Planck constant, ν the frequncy of microwave used, β the Bohr magneton, and g the spectroscopic splitting factor which ranges from 2.0 to 2.4. In these salts, other than from ions of non-equivalent orientation in unit cell, there appears one peak and its resonance field H varies in proportion to the frequency ν of the *rf*-field. This can be deduced from the fact that the copper ion has $(3d)^9$ electronic configuration, *i.e.*, one electron missing from the complete $3d$ shell. So, under an influence of a crystalline field, it leaves a Kramers' doublet ($S=1/2$) as the lowest ground state. Resonance transition occurs between levels of the doublet, their splitting being in proportion to the applied magnetic field.

On the other hand, copper acetate monohydrate has a quite different appearance its paramagnetic resonance spectra whi resemble somewhat to the spectra of hydrat nickel salts having spin triplet ($S=1$). R sonance peaks observed in copper acetate ca be well fitted to an effective spin Hamiltonia

$$\mathscr{H} = g\beta\vec{H}\vec{S} + D\left\{S_z^2 - \frac{1}{3}S(S+1)\right\} + E(S_x^2 - S_y^2) \qquad (2$$

with two paramagnetic units in unit cell. D tailed resonance measurements were achiev at four different frequency bands to determi parameters appearing in the spin Hamiltoni and directions of three principal axes of cr stalline field (z, x and y).

§ 2. Experimental

Single crystals of copper acetate mon

hydrate were prepared by means of the vaporization method from aqueous solution. They belong to the monoclinic system having parameters[1] of

$$a:b:c=1.5320:1:0.8108, \text{ and } \beta=116°26'$$

and show themselves as twins arround $(20\bar{1})$ plane, the twinning plane. This twinning plane is expressed as $(10\bar{1})$ plane refered to the unit cell determined by X-ray crystallography which was given by Kiriyama *et al*[2] as

$$a=13.10\text{ Å},\quad b=8.56\text{ Å},\quad c=13.88\text{ Å}$$
$$\text{and } \beta=116°26'$$

and by van Niekerk and Schoening[3] as

$$a=13.15\text{ Å},\quad b=8.52\text{ Å},\quad c=13.90\text{ Å}$$
$$\text{and } \beta=117°0'$$

Since the detailed descriptions on our experimental apparatus will be reported elsewhere[4], only a slight glance is given here. By crystal multipliers, higher harmonics were produced from the fundamental 3-cm wave supplied by a 2K25-type klystron. The 2nd, 3rd and 4th order hormonic was separately utilized as our *rf*-power source of $\lambda=16$, 10, and 8 mm wave, respectively.

Microwave power with appropriate frequency goes through attenuators to the silicon diode after transmitting through a cavity resonator containing the sample crystal. The rectified current of the diode is then fed to a sensitive galvanometer. Resonance absorption causes galvanometer deflection decrease as a function of the static magnetic field applied. Some examples are shown in Fig. 1. The magnetic field strength H corresponding to the maximum decrease in galvanometer deflection was determined as a function of the *rf*-frequency and of the direction in which the static field was applied. Between the observed values of resonance peaks and the calculated ones, the best fit is obtained when the parameters appearing in the Hamiltonian (2) are determined as listed in Table I. Experimental results reported in our preliminary works[5][6] were also used to determine the proper values of parameters in the Table. This Table also contains the parameters given by Bleaney and Bowers[7][8] which were determined from their experiments at 90°K. From the spectra of paramagnetic resonance, orientations of three mutually perpendicular (z, x, and y) axes of crystalline field acting on copper ions can be determined refering to the crystallographic axes. Experimental results show the existence of a pair of paramagnetic units in unit cell, where the magnetic unit consists of two copper ions. One of the magnetic units can be derived from the other by an operation of mirror reflection with the *ac*-plane. The results are given in Table II, where angles ψ and α have the following definitions: ψ means the angle between the c-axis and the projection of the two z-axes on the *ac*-plane, measured from the c-axis towards the $+a$-axis whereas α means the angle between the z-axes and the *ac*-plane. This orientation may be considered to be that of a line joining the two copper ions in the

unit. In Table II, the angles indicating this direction which were obtained by the methods other than the paramagnetic resonance, are also listed: X-ray cristallography and static susceptibility. There comes some complexity from the twinning character of this crystal. Considerations were put on this twinning character to prepare the Table II.

§ 3. Discussions

From the measured spectra of paramagnetic resonance absorption, a conclusion can be deduced that there must be clusters of copper ions having a strong interaction within ions in pair.

The effective spin Hamiltonian (2) can be deduced[8] by combining two Hamiltonians $\mathscr{H}_1$ and $\mathscr{H}_2$ which describe isolated copper ions under cristalline field X and a dot type exchange term $J\vec{S}_1\vec{S}_2$

$$\mathscr{H}=\mathscr{H}_1+\mathscr{H}_2-J\vec{S}_1\vec{S}_2 \qquad (3)$$

where

$$\mathscr{H}_i=X_i+\lambda\vec{L}_i\vec{S}_i+\beta\vec{H}(\vec{L}_i+2\vec{S}_i) \qquad (i=1 \text{ or } 2) \quad (4)$$

The parameter D in the effective Hamiltonian can be derived[8] from these equations as

$$D=-\frac{J}{8}\left[\frac{1}{4}(g_{//}-2)^2-(g_{\perp}-2)^2\right] \qquad (5)$$

Using parameters in Table I, exchange energy J can be estimated. Our results at room temperature give $|J_{300}|=116\,\text{cm}^{-1}$ whereas Bleaney and Bowers' give $|J_{90}|=73\,\text{cm}^{-1}$. Taking account of the range of errors (containing neglection of rhombic part of the crystalline field), J_{300} ranges from 95 to 140 cm^{-1} and J_{90} from 62 to 87 cm^{-1}. These results show the exchange energy between two copper ions increases with temperature. Assumption of isotropic thermal expansion gives the reverse temperature variation in exchange energy. To explain this reverse temperature dependence, anisotropic thermal expansion must be assumed causing a thermal contraction between two copper ions. If the exchange inte

action between two directly interacting copp

ions can be assumed to obey to the Bor

Mayer's relation,

$$J\propto \exp\,(-\varDelta R/0.345) \qquad (6$$

there must be a contraction of order of 4

$=-0.027$ Å in the distance between the cop

ions in pair when the temperature of cryst

changes from 90°K to 300°K. Although t

value itself is not so unreasonable one but

expected order from the view-point of therm

expansion, it is somewhat doubtful wheth

the difference of J has a physical meaning

not.

A survey on the variation of absorpti

intensity of each lines will be reported els

where.[10]

Studies on the Magnetic Anisotropy Induced by Cold Rolling of Ferromagnetic Crystal (I) Iron-Nickel Alloys

By Sōshin CHIKAZUMI, Kenzō SUZUKI and Hiroko IWATA

Department of Physics and Chemistry, Gakushuin University, Mejiro, Tokyo, Japan

(Received August 2, 1957)

Investigation was made on the magnetic anisotropy induced by mechanical rolling of ferromagnetic alloys. Experiments were carried out on the single crystals of Ni_3Fe through observation of magnetic domain patterns and torque measurements. Easy magnetizing direction was found to be normal to the roll direction for (110) [001] and (001) [100] rolling, while it changes to parallel to roll direction at about 30% reduction for (001) [110] rolling. The maximum value of uniaxial anisotropy was $2 \sim 3 \times 10^5$ erg/cc. The results were satisfactorily explained by assuming the appearance of directional order by slip deformation. It was shown theoretically that the anisotropies thus induced are classified into long range order (fine slip) type and short range order (coarse slip) type. Relation to the superlattice formation was also discussed.

§ 1. Introduction

It is well known that iron-nickel alloys develop a large magnetic anisotropy when they are plastically deformed by rolling or stretching. Isoperm is a magnetic material treated in this manner. This phenomenon was first found by W. H. Six, J. L. Snoek and W. G. Burgers[1] in 1934. Detailed investigations were reported by H. W. Conradt, O. Dahl and K. Sixtus[2] in 1940 and by G. W. Rathenau and J. L. Snoek[3] in 1941. It was confirmed by these investigators that the magnetic anisotropy induced by rolling (roll anisotropy) is not merely related to a magnetostriction and internal stress nor to a crystal magnetic anisotropy.

Recently L. Néel[4] and independently S. Taniguchi and M. Yamamoto[5] interpreted the mechanism of this anisotropy in terms of the "directional order" or "orientational superlattice" which means an asymmetrical distribution of AA, BB and AB atom pairs in the solid solution of A and B atoms. Their theories are based upon the idea that a directional order would be induced by a strong stress exerted during rolling or stretching, where atom migration during plastic deformation plays an important role in bringing the atoms into their stable positions.

On the other hand, it was confirmed by one of the present authors and T. Oomura[6] that a roll anisotropy reported by Rathenau and Snoek is quite similar to the anisotropy due to magnetic annealing in their dependence on the alloy composition. This fact also confirms us in the view that the origin of roll anisotropy is closely related to the directional order, as is the case for magnetic annealing.[4],[5],[7]

The present investigation was made for the purpose of making out the true mechanism of the appearance of directional order by plastic deformation. Experiments were carried out on several sorts of single crystal and polycrystal through observation of magnetic domain patterns and measurement of magnetic anisotropy energy. The results were satisfactorily explained by assuming that the directional order are induced by slip deformation. It was theoretically expected that the anisotropy thus induced can be classified into two types i.e. long range order (fine slip) type and short range order (coarse slip) type. Calculations along this concept are found to be in good agreement with experimental facts.

§ 2. Specimens and Experimental Procedure

Specimens used in this experiment were prepared by melting electrolytic iron and nickel in a high vacuum induction furnance. Large crystals were obtained by solidifying the alloy slowly in a crucible. This procedure was carried out first in a molybdenum wire resistance furnace, but recently in a high vacuum induction furnace. These crystals were cut into rectiangular plates having desired crystallographic orientation. The size of the specimen was 10 ~ 20 mm in length, 3 ~ 5 mm in width and 1 ~ 2 mm in thickness. In some cases thick pieces of single crystal (2 ~ 3mm in thickness) were used in order to observe the domain pattern on the thin edge.

Specimens were in some cases previously quenched from 700°C to attain the disorder state or annealed for 200 hours at from 490° to 430° to attain the prefect order state. The specimen indicated by "slow cool" is that which was cooled naturally in a cruicible before shaping.

Cold work on the specimen was carried out by a small rolling machine with rollers of 50 mm in diameter, which rotate at 11 r.p.m. A reduction of the thickness by one pass was about 0.03 mm.

Domain patterns were observed by means of the usual powder pattern technique with a light electrolytic polishing of the rolled surfaces.

Measurement of the magnetic anisotropy was carried out in various ways. For (110) [001] rolling, the anisotropy was determined by the measurement of magnetization curve by using long specimens. Since the easy direction in this case is normal to the roll direction, magnetization takes place by rotation and therefore gives rise to a linearly inclined magnetization curve. The anisotropy was obtained from the inclination of the linear part. In the case of the polycrystal, long specimens were cut from the rolled sheet, one in parallel and the other in perpendicular to the roll direction. The anisotropy was determined by the comparison of the magnetization curves for both specimens.

Exact determination of the anisotropy was made by means of the torque measurement. Specimens for this were cut in a shape of circular plate from the rolled single crystal. In some cases successive rolling and shaping were made on a circular specimen for the purpose of measuring the torque as a function of roll reduction. The size of the specimens was 3 ~ 13 mm in diameter.

Composition of the specimens used in the present experiment was restricted to Ni_3Fe where the superlattice formation is most effective, because the dependence of the anisotropy on the composition has been known to be simple as reported by Rathenau an
Snoek.

§ 3. Experimental Results

(1) (110) [001] rolling

Simple and well-defined domain pattern
were observed on the rolled crystal surfac
(110), when the direction of rolling is paralle
to [001]. Pl. 1, 2, 3, 4, 5 and 6 are the serie
of the photographs in the course of rolling
For more than 30% reduction, many domain
divided by 180° walls which are running i
perpendicular to the roll direction appeare
Although the pattern becomes more an
more clear as the reduction increases, th
essential feature does not change until 94
reduction. Even when the roll directio
rotates to the other direction in the sam
plane, the direction of domain magnetizatio
is also parallel to the same crystallographi
direction $[1\bar{1}0]$. The patterns for $[1\bar{1}2]$ an
$[1\bar{1}0]$ roll are shown in Pl. 7 and 8.

The anisotropy energy in this case wa
determined from magnetization curve. Sinc
the magnetization takes place by rotation, th
magnetization curve is linearly inclined on

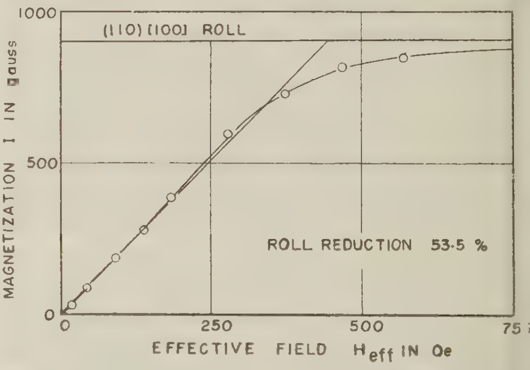

Fig. 1. Magnetization curve for rolled (110) [001
crystal. Specimen was previously cooled slowly. Reduction is 53.5%.

as shown in Fig. 1. The coefficient o
uniaxial anisotropy K_u (cf. Eq. (32)) is cal
culated from the inclination of the linea
part. The results are summarized in Fig.
for variously treated specimens as a functio
of roll reduction. The point marked by dou
ble circle is obtained from torque measure
ment, being in good agreement with tha
obtained from magnetization curve. It i
interesting to note that a curve for slowl

cooled specimen, for annealed for 1 hour at 490°C and a point for quenched from 700°C are in good coincidence with one another, whereas the curve for perfectly ordered specimen shows a very slow development of the anisotropy. The domain patterns for perfect ordered crystal are shown in Pl. 9 and Pl. 10. Zigzag character of the pattern in Pl. 9 may be due to the relatively large crystal anisotropy energy (~ 3×10^4 erg/cc) of the perfect order state. Uniaxial domains similar to Pl. 3~6, however, appeared at the later stage of rolling (Pl. 10).

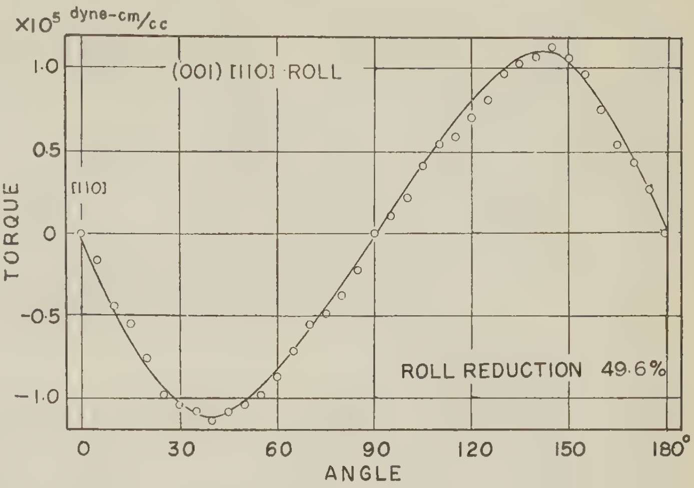

Fig. 3. Torque curve for rolled (001) [110] crystal. Specimen was previously in a perfect order state. Roll reduction is 49.6%.

(2) (001) [110] rolling

The domain patterns appearing on the rolled surface are not so simple as to allow a straightforward interpretation as shown in Pl. 11, 12, 13 and 14. We could observe, however, well-defined domain patterns on the thin edge of the rolled plate as shown in Pl. 15 and 16. It is interesting that the patterns of the upper and lower half of the side surface are symmetrical with respect to the intermediate plane, corresponding to the slip bands which are observed on the same surface as are shown in Pl. 27 and 28. The black and white strips are the uniaxial domains, whose direction rotates gradually to a horizontal direction as the reduction increases. It is concluded that the very small spikes observed on the rolled surface (Pl. 13 and 14) are the reverse domains which are responsible to the reduction of a magnetostatic energy. It is observed that the spikes become longer and longer as the basal domains rotate to make the smaller angle to the surface.

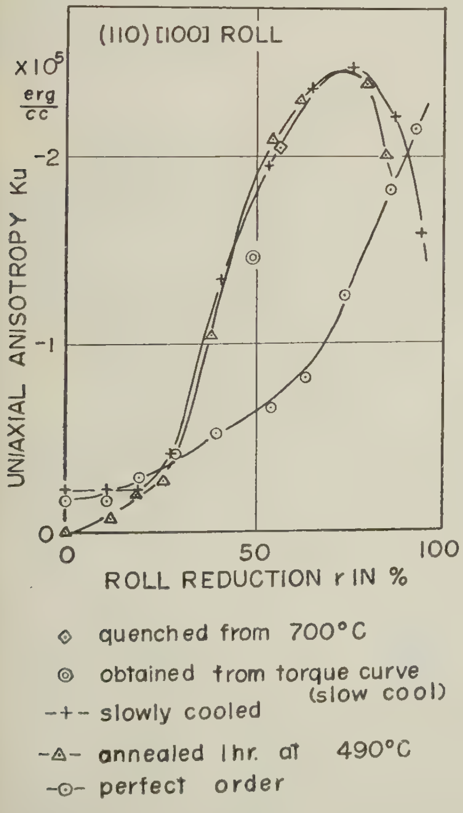

Fig. 2. Coefficient of anisotropy as a function of roll reduction. Specimens are (110) [001] crystals, previously heat-treated as indicated.

Anisotropy energy in the rolled surface was measured by means of torque magnetometer by using a circular plate. One example of the torque curve is shown in Fig. 3. Since this curve includes a small amount of crystal anisotropy K_1 term, the uniaxial term K_u was calculated by eliminating the K_1 term by the Fourier analysis. K_1 was less than 0.02×10^6 erg/cc for slowly cooled specimen and equal to 0.25×10^5 erg/cc for perfectly ordered one.

K_u is graphically shown in Fig. 4 as a function of roll reduction. It is interesting that K_u is at first negative (easy direction being normal to roll direction), while it changes its sign to positive (easy direction being parallel to roll direction) at about $r=20\sim30\%$. Increase of K_u in positive sense for larger reduction corresponds to rotation of uniaxial domain to the roll direction, as is observed in the domain pattern.

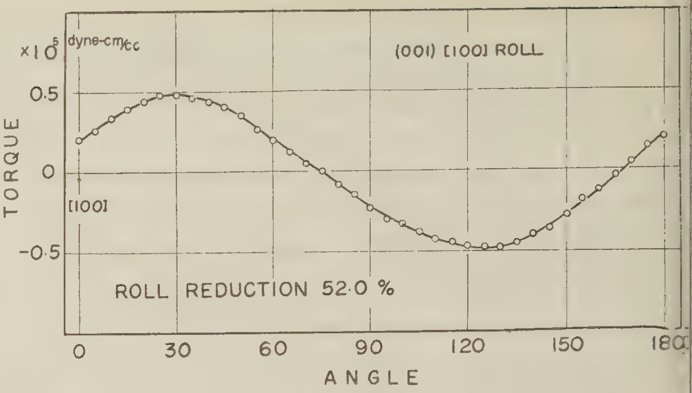

Fig. 5. Torque curve for rolled (001) [100] crystal. Specimen was previously cooled slowly. Roll reduction is 52.0%

(3) (001) [100] rolling

The crystallographic orientation in this case is the same as that of recrystallization texture which is applied to the "isoperm". The torque curve is shown in Fig. 5, which proves that the easy direction is nearly normal to the roll direction as is well known for isoperm. The value of K_u obtained from this curve is -0.48×10^5 erg/cc for $r=52\%$, which is also in good agreement with the value obtained by Rathenau and Snoek. The domain pattern in this case, however, is very complicated as shown in Pl. 17, 18 and 19. The patterns on the thin edge have the character similar to the patterns observed on the basal plane of cobalt (Pl. 20 and 21). The star-like patterns in these plates prove that the domain direction strikes the side surface at a deep glancing angle. Patterns on the rolled surface at latter stage of rolling (Pl. 19) shows a gradual approach of the domain direction to the roll surface (normal to the roll direction.).

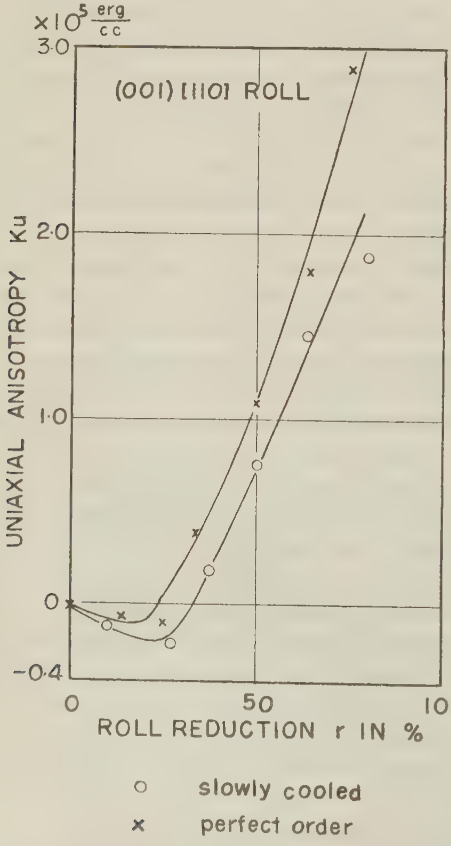

Fig. 4. Coefficient of uniaxial anisotropy as a function of roll reduction for (001) [110] rolling.

(4) Polycrystal

The domain patterns for rolled polycrystal are shown in Pl. 22, 23 and 24, in which numerous uniaxial domains are observed in the individual crystallites. It is recognized that there are statistically many domains which have the magnetization parallel to roll

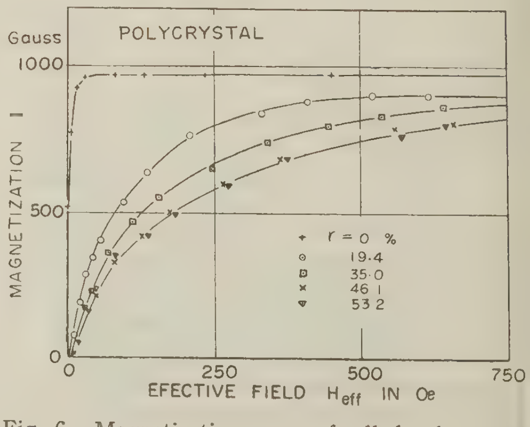

Fig. 6. Magnetization curve of rolled polycrystal measured by applying the filed normal to the roll direction. Specimen was annealed for 100 hours at 490°C.

direction. This is also confirmed by the measurement of magnetization curve. Fig. 6 is a variation of magnetization curve which is measured by applying the field normal to the roll direction.

The work necessary to magnetize to saturation are shown in Fig. 7 as a function of roll reduction for parallel- and perpendicular-cut specimens. The fact that the energy is larger for perpendicular cut than for parallel cut specimen means that the average easy direction is parallel to the roll direction. This fact was also reported by Rathenau and Snoek. It should be noted that the anisotropy energy in this case increases with a progress of order formation, on the contrary to the (110) [001] case. Moreover it should be added that stress hardening increases considerably with a progress of order formation, so that the perfectly ordered specimen was broken at their crystal boundaries by the rolling of only 10% reduction (Cf. Pl. 25). This was not the case for any single crystals.

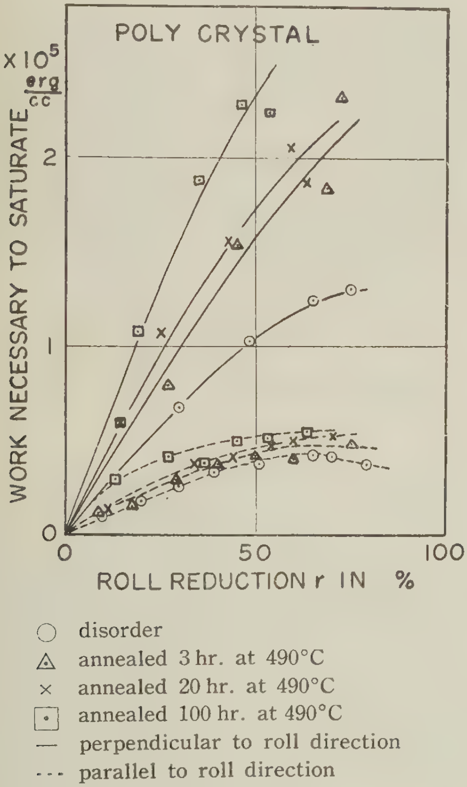

Fig. 7. Comparison of the energy necessary to magnetize to saturation between parallel and perpendicular-cut specimens of rolled polycrystal. Crystal was previously heat-treated as indicated.

§4. The Mechanism of Appearance of Magnetic Anisotropy due to Slip Deformation

In this section we shall deal with the calculation of magnetic anisotropy induced by slip deformation. Now the dipole-dipole interaction between neighboring atomic moments gives rise to the energy

$$w_i = l\cos^2\varphi_i\,, \qquad (1)$$

where φ_i is the angle between magnetization and pair direction. This energy, however, does not give rise to any anisotropy energy as far as the orientational distribution of the atomic pairs is of a cubic symmetry. If, however, the coefficient l takes the different values l_{AA}, l_{BB} and l_{AB} for AA, BB and AB pairs respectively in the solid solution containing A and B atoms, unbalanced distribution of these atomic pairs (directional order) should give rise to the anisotropy energy. Since N_{AAi}, N_{BBi} and N_{ABi}, the numbers of AA, BB and AB pairs per unit volume having i-th bond direction, are related to N_A and N_B, i.e. the numbers of A and B atoms in a unit volume, by

$$\left.\begin{aligned} 2N_{AAi}+N_{ABi}&=2N_A \\ 2N_{BBi}+N_{ABi}&=2N_B \end{aligned}\right\}, \qquad (2)$$

we can express the anisotropy energy by the form which includes only N_{BB}, namely

$$\begin{aligned} E&=\sum_i (N_{AAi}l_{AA}+N_{BBi}l_{BB}+N_{ABi}l_{AB})\cos^2\varphi_i \\ &=\sum_i N_{BBi}(l_{AA}+l_{BB}-2l_{AB})\cos^2\varphi_i+\text{const.} \\ &=l\sum_i N_{BBi}\cos^2\varphi_i+\text{const.}\,, \end{aligned} \qquad (3)$$

where

$$l=l_{AA}+l_{BB}-2l_{AB}\,. \qquad (4)$$

For iron-nickel alloys the numerical value of l has been estimated by Néel[4] from the magnetostriction data as

$$Nl=N(l_{NiNi}+l_{FeFe}-2l_{FeNi})=3\cdot1\times10^8 \text{ erg/cc}, \qquad (5)$$

where N is the total number of atoms in a unit volume.

Next we shall calculate the distribution of BB pairs induced by slip deformation. It was found that the directional order thus induced can be classified into two types according as the travelling of atoms by the slip is confined within an original order domain or extends to another order domain of the opposite side of the slipped plane.

(a) Anisotropy of Long Range Order (Fine Slip) Type

Fig. 8 shows the long range ordered A_3B type lattice (face-centered cubic) which is deformed by one-step slip along (111) plane in the direction of $[01\bar{1}]$. Although no BB pairs are found in the non-deformed part, it is recognized in the figure that many BB pairs which direct to [011] appeared at the slipped part. We shall calculate the number of BB pairs thus induced. It is verified by simple calculation that the number of B atoms occupied at β-sites on a unit area of (111) plane is larger by $S/\sqrt{3}\,a^2$ than that of α-sites, where S is the degree of long range order and a is the lattice constant. The number of BB pairs induced per unit area of (111) plane is thus given by $p_0S^2/2\sqrt{3}\,a^2$ on the average, where the factor 1/2 comes from the fact that a chance of appearance of BB pairs are limited to the case that the slip is made by the displacement of the odd number of dislocations. It is, however, generally accepted that the dislocations tend to move as in pairs in the ordered crystal so as to recover the ordered state.[8] On this reason the probability p_0, that a dislocation does not become in pairs with another one, was introduced in the above expression.

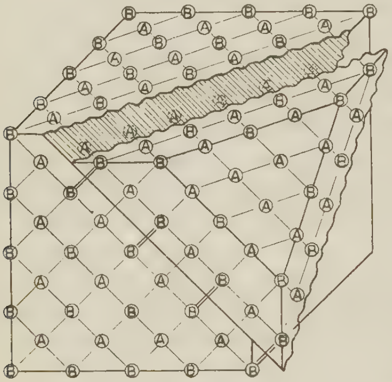

Fig. 8. Appearance of BB pairs by one-step slip along (111) plane in the direction $[01\bar{1}]$ in the long range ordered A_3B type lattice.

Now let us suppose that ns dislocations passed per n atomic planes which belong to the referred slip system. We shall call s as "slip density" hereafter. Then the number of slipped planes is given by $\sqrt{3}\,p'|s|/a$ per unit depth, where p' is the probability for one dislocation to start in a virginal atomic plane. The total number of BB pairs for i-th slip system is given by

$$N_{BBi}=\frac{p_0S^2}{2\sqrt{3}\,a^2}\times\frac{\sqrt{3}\,p'|s_i|}{a}$$
$$=\frac{1}{8}NpS^2|s_i|\,, \tag{6}$$

where

$$p=p_0p'\,. \tag{7}$$

In face-centered crystal the slip plane is known to be {111} and the slip direction is to be ⟨110⟩, so that the total number of slip systems is 4×3=12. The direction cosines of BB pairs induced by the slips of individual slip system i (β_{1i}, β_{2i}, β_{3i}) are given in Tab. I. By using the direction cosines (α_1, α_2, α_3) of the inner magnetization together with (β_{1i}, β_{2i}, β_{3i}) and Eq. (6), Eq. (3) becomes

$$E=\frac{1}{8}NlpS^2\sum|s_i|(\alpha_1\beta_{1i}+\alpha_2\beta_{2i}+\alpha_3\beta_{3i})^2$$
$$=\frac{1}{8}NlpS^2\sum|s_i|f_i(\alpha_1,\ \alpha_2,\ \alpha_3)\,, \tag{8}$$

where

$$f_i(\alpha_1,\alpha_2,\alpha_3)=\beta_{1i}^2\alpha_1^2+\beta_{2i}^2\alpha_2^2+\beta_{3i}^2\alpha_3^2$$
$$+2\beta_{2i}\beta_{3i}\alpha_2\alpha_3+2\beta_{3i}\beta_{1i}\alpha_3\alpha_1$$
$$+2\beta_{1i}\beta_{2i}\alpha_1\alpha_2\,. \tag{9}$$

The coefficient of each term in $f_i(\alpha)$ is also tabulated in Tab. I for every slip systems.

It should be added that this type of anisotropy should be induced irrespective of the degree of order, as far as the slip distance per one atomic plane is less than the diameter of the antiphase order domain (fine slip).

(b) Anisotropy of Short Range Order (Coarse Slip) Type

When many dislocations pass through a definite atomic planes so as to bring the one side of the crystal to the out of phase order domain of the opposite side of the crystal, it is expected that the directions of the induced BB pairs are different from that given in Fig. 8. In the case of $(111)\,[01\bar{1}]$ slip the directions of BB pairs is [011], [101] or [110] or they disappear, depending upon the sorts of antiphase domain and upon the number of dislocations. It is easily verified that the

Table I. Direction cosines of BB pairs and the coefficients of each term in $f_i(\alpha_1, \alpha_2, \alpha_3)$ in the expression of long range order (fine slip) type anisotropy. Cf. Eq. (9).

9		[011]	$0,$	$\frac{1}{\sqrt{2}},$	$-\frac{1}{\sqrt{2}}$	0	$\frac{1}{2}$	$\frac{1}{2}$	-1	0	0
10	$(\bar{1}11)$	$[01\bar{1}]$	$0,$	$\frac{1}{\sqrt{2}},$	$\frac{1}{\sqrt{2}}$	0	$\frac{1}{2}$	$\frac{1}{2}$	1	0	0
11		[101]	$\frac{1}{\sqrt{2}},$	$0,$	$-\frac{1}{\sqrt{2}}$	$\frac{1}{2}$	0	$\frac{1}{2}$	0	-1	0
12		[110]	$\frac{1}{\sqrt{2}},$	$-\frac{1}{\sqrt{2}},$	0	$\frac{1}{2}$	$\frac{1}{2}$	0	0	0	-1

probability of finding one case among these four cases is equally 1/4. Since the probability of finding BB pairs among the atomic pairs which have a certain bond direction is also 1/4 in the disordered state, we can regard the distribution of atomic pairs which connect the both sides of the slipped plane as disordered one. Now let us suppose that the crystal was previously in the partially ordered state, which is characterized by σ the degree of short range order. It is easily verified that the number of BB pairs lying in a unit area of (111) plane is $(1-\sigma)/(4\sqrt{3}a^2)$, which is smaller by $\sigma/(4\sqrt{3}a^2)$ than that of disorder state. Then it follows that the number of BB pairs connecting the both sides of the slipped plane is larger by $\sigma/(4\sqrt{3}a^2)$ per unit area of (111) plane than before the slip takes place. Thus the number of BB pairs induced by the slips in a unit volume is given by

$$N_{BB\,i}=\frac{\sigma}{4\sqrt{3}\,a^2}\times\frac{\sqrt{3}\,p'|s_i|}{a}$$

$$=\frac{1}{16}Np'\sigma|s_i|\,. \tag{10}$$

Since the bond direction of BB pairs thus induced is [011], [101] or [110], the average interaction energy becomes

$$w=\frac{l}{3}(\cos^2\varphi_{[011]}+\cos^2\varphi_{[101]}+\cos^2\varphi_{[110]})$$

$$=\frac{l}{3}\sum_{k=1,2,3}(\beta_{1k}\alpha_1+\beta_{2k}\alpha_2+\beta_{3k}\alpha_3)^2$$

$$=\frac{l}{3}(\alpha_2\alpha_3+\alpha_3\alpha_1+\alpha_1\alpha_2)+\text{const.} \tag{11}$$

This functional form means that the slip plane (111) is an easy magnetizting plane and a normal to it is a hard direction, provided $l>0$. Then the interaction energy for i-th slip system whose slip plane's normal is (n_{1i}, n_{2i}, n_{3i}) becomes

$$w_i=l(n_{2i}n_{3i}\alpha_2\alpha_3+n_{3i}n_{1i}\alpha_3\alpha_1+n_{1i}n_{2i}\alpha_1\alpha_2). \tag{12}$$

The resultant anisotropy is

$$E=\sum_i N_{BB\,i}\,w_i$$

$$=\frac{1}{16}Nlp'\sigma\sum_i|s_i|\,g_i(\alpha_1,\ \alpha_2,\ \alpha_3)\,, \tag{13}$$

Table II. Direction cosines of the normal of slip plane and coefficient of each term in $g_i(\alpha_1, \alpha_2, \alpha_3)$ in the expression of short range order (coarse slip) type anisotropy. Cf. Eq. (14).

No. of Slip System	n_1,	n_2,	n_3	Coefficients in $g(\alpha_1\alpha_2\alpha_3)$

12		〃		$\frac{1}{3}$	$-\frac{1}{3}$	$-\frac{1}{3}$

where

$$g_i(\alpha_1, \alpha_2, \alpha_3) = n_{2i}n_{3i}\alpha_2\alpha_3 + n_{3i}n_{1i}\alpha_3\alpha_1 + n_{1i}n_{2i}\alpha_1\alpha_2. \quad (14)$$

The coefficients of each term in (14) are tabulated in Tab. II for every slip systems.

It should be noted that this type of anisotropy should be induced irrespective of the degree of order as far as the slip distance is larger than the diameter of antiphase order domain.

§ 5. Calculation of Slip Deformation

In order to calculate the magnetic antisotropy for individual rolling cases from Eq. (8) or (13), it is necessary to determine the value of slip density $|s_i|$ for every slip systems. The deformation by (110) [01$\bar{1}$] slip system (No. 1) is shown in Fig. 9. By considering that the distance of atomic plane is $a/\sqrt{3}$ and length of one step of slip (Burger's vector) is $a/\sqrt{2}$, it is easily verified that the components of strain tensor are given by

$$\left.\begin{array}{lll} \gamma_{xx1}=0, & \gamma_{yy1}=s_1, & \gamma_{zz1}=-s_1 \\ \gamma_{yz1}=0, & \gamma_{zx1}=-s_1/2, & \gamma_{xy1}=s_1/2 \end{array}\right\}, \quad (15)$$

where s_1 is the slip density as defined in § 4 (a). The strain tensors for the other slip systems are similarly calculated and tabulated in Tab. III. The resultant deformation is

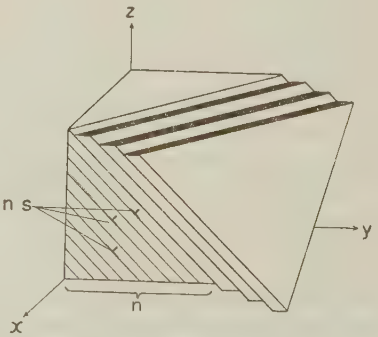

Fig. 9. Deformation by the slips which belong to (110) [01$\bar{1}$] slip system.

Table III. Components of strain tensor for every slip systems.

9	0	$-S_9$	S_9	0	$\frac{1}{2}S_9$	$-\frac{1}{2}S_9$
10	0	S_{10}	$-S_{10}$	0	$\frac{1}{2}S_{10}$	$-\frac{1}{2}S_{10}$
11	S_{11}	0	$-S_{11}$	$-\frac{1}{2}S_{11}$	0	$-\frac{1}{2}S_{11}$
12	$-S_{12}$	S_{12}	0	$\frac{1}{2}S_{12}$	$\frac{1}{2}S_{12}$	0

given by

$$\left.\begin{array}{lll}\gamma_{xx}=\sum_i \gamma_{xx\,i}, & \gamma_{yy}=\sum_i \gamma_{yy\,i}, & \gamma_{zz}=\sum_i \gamma_{zz\,i} \\ \gamma_{yz}=\sum_i \gamma_{yz\,i}, & \gamma_{zx}=\sum_i \gamma_{zx\,i}, & \gamma_{zy}=\sum_i \gamma_{xy\,i}\end{array}\right\}. \quad (16)$$

(1) (110) [001] rolling

It is assumed that the rolling of the specimen plate results in an elongation in length and a reduction in thickness but no widening of the specimen width. This assumption is exactly reallized in the (110) [001] rolling, although there are some exceptional cases which will be mentioned later. Then the tensor components with respect to the coordinate fixed to the crystal should be given by

$$\left.\begin{array}{lll}\gamma_{xx}=-r, & \gamma_{yy}=-r, & \gamma_{zz}=2r \\ \gamma_{yz}=0, & \gamma_{zy}=0, & \gamma_{xy}=-r\end{array}\right\}, \quad (17)$$

where r is the reduction in thickness.

It should be expected that the slip systems contributing to this deformation are No. 1, 2, 4 and 5 (i.e. that of (111) and (111) slip plane), because the others have the slip planes normal to the roll plane and the slip along them should not contribute in reducing the thickness (Cf. Fig. 10). If it is true, the rolling in any direction for (110) plate might always induce the preferred elongation in the direction [001]. In fact it was observed that the specimen having different crystallographic direction are rolled into the various shapes as shown in Fig. 11, which are found to be caused by the preferred elongation in [001].

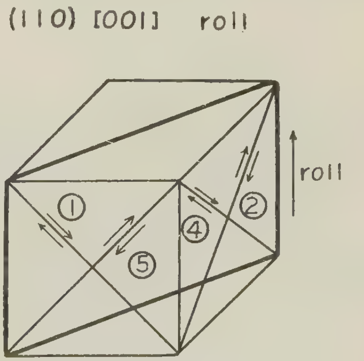

Fig. 10. The slip systems contributing to (110) [001] roll.

Then the strain components are expressed in terms of s_i's by referring Tab. III. Thus we have

$$\left.\begin{aligned}\gamma_{xx}&=-s_2+s_4\,,\\ \gamma_{yy}&=s_1-s_5\,,\\ \gamma_{zz}&=-s_1+s_2-s_4+s_5\,,\\ \gamma_{yz}&=\tfrac{1}{2}(s_2+s_4)\,,\\ \gamma_{zx}&=\tfrac{1}{2}(-s_1-s_5)\,,\\ \gamma_{xy}&=\tfrac{1}{2}(s_1-s_2+s_4-s_5)\end{aligned}\right\}. \tag{18}$$

By assuming the symmetry consideration, i.e.

$$s_1=-s_2=s_4=-s_5\,, \tag{19}$$

we have by the comparison between (17) and (18)

$$s_1=s_4=-r/2,\quad s_2=s_5=r/2\,. \tag{20}$$

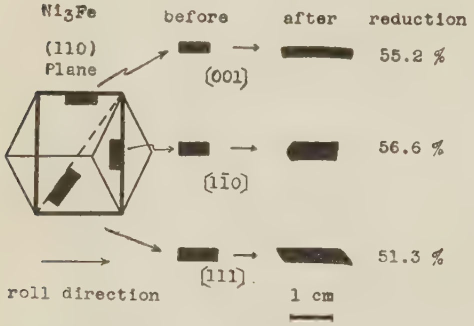

Fig. 11. Change of shapes of the specimens cut from (110) plate by the rolling along various direction.

(2) (001) [110] rolling

The deformation for this case should be given by

$$\left.\begin{matrix}\gamma_{xx}=r, & \gamma_{yy}=r, & \gamma_{zz}=-2r\\ \gamma_{yz}=0, & \gamma_{zx}=0, & \gamma_{xy}=r\end{matrix}\right\}. \tag{21}$$

The slip systems which can contribute for this deformation are also No. 1, 2, 4 and 5, but the real contribution was made only by No. 1 and 2. This is because the slips in this case are made by easy glide. Pl. 27 and 28 are the microphotographs of the slip bands appearing on the thin edge of the specimen. It can be seen in the plates that easy glide takes place in the upper and lower halves of the crystal and the slip bands in each region rotate to the roll direction with a progress of rolling. The reason why easy glide takes place in this case is as follows: In this case the slip plane (111) makes the angle of 54.5° with rolling plane (Fig. 13), and therefore the slip along it causes the rotation of the crystal which results in a decrease of the angle from 54.5°. This chang of orientation results in an increase of th shearing stress component along its slip plan and thus favors the slips along itself. I the case of (110) [001] rolling, however, (11 slip plane makes the angle of 35.5° with ro plane and the slip along it results in a decrerse of angle from 35.5°. This crystal rotation disfavors the original slips and favors the slip along another slip plane (11$\bar{1}$), resulting in the both slips as assumed in §5 (1).

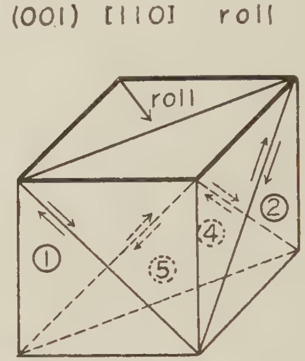

Fig. 12. The slip systems contributing to the (001) [110] rolling.

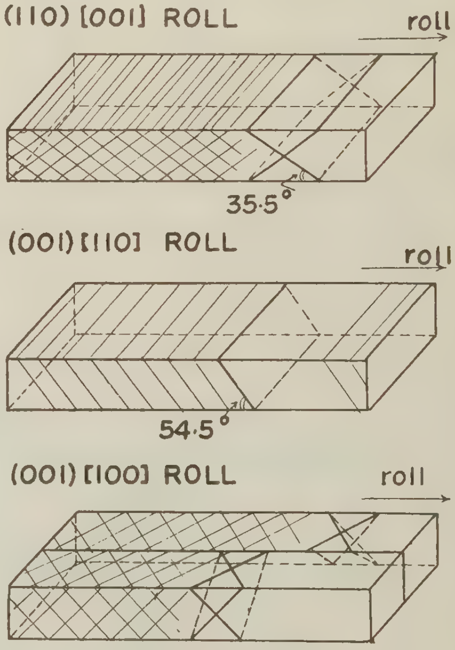

Fig. 13. Actual slips by the rolling in various crystallographic direction.

The deformation is given by

$$\left.\begin{aligned} &\gamma_{xx}=-s_2\,, \\ &\gamma_{yy}=s_1\,, \\ &\gamma_{zz}=-s_1+s_2\,, \\ &\gamma_{yz}=\tfrac{1}{2}s_2\,, \\ &\gamma_{zx}=-\tfrac{1}{2}s_1\,, \\ &\gamma_{xy}=\tfrac{1}{2}(s_1-s_2) \end{aligned}\right\} . \tag{22}$$

By comparing (22) with (21), we have

$$s_1=r\,,\quad s_2=-r\,, \tag{23}$$

although they do not give the right values for γ_{yz} and γ_{zx}.

For the under half of the crystal where effective slip systems are No. 4 and 5, we have

$$s_4=r\,,\quad s_5=-r\,. \tag{24}$$

(3) (001) [100] rolling

The deformation for this case should be

$$\left.\begin{aligned} &\gamma_{xx}=2r, \quad \gamma_{yy}=0, \quad \gamma_{zz}=-2r \\ &\gamma_{yz}=0, \quad \gamma_{zx}=0, \quad \gamma_{xy}=0 \end{aligned}\right\} . \tag{25}$$

The slip systems which contribute to the deformation are No. 2, 4, 8 and 11, because No. 3, 6, 7 and 12 should not contribute in reducing the thickness and No. 1, 5, 9 and 10 should cause the widening of the specimen width. In this case the easy glide is also expected, because the slip by No. 2 causes the crystal rotation which favors No. 2 itself and No. 11 and disfavors No. 4 and No. 8. The calculation is given in Appendix. It is, therefore, probable that the slips by both No. 2 and No. 11 take place in some places and those by both No. 4 and No. 8 in the other places (Cf. Fig. 13). The slip bands in this cases are shown in Pl. 29 and 30.

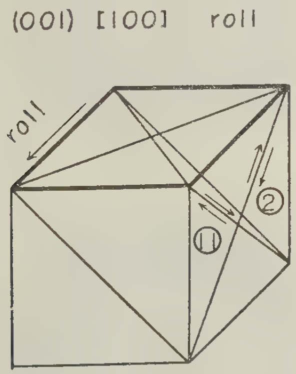

Fig. 14. Slip systems which contribute to the (001)[100] rolling.

The deformation due to No. 2 and No. 11 is given by

$$\left.\begin{aligned} &\gamma_{xx}=-s_2+s_{11}\,, \\ &\gamma_{yy}=0\,, \\ &\gamma_{zz}=s_2-s_{11}\,, \\ &\gamma_{yz}=\tfrac{1}{2}(s_2-s_{11})\,, \\ &\gamma_{zx}=0\,, \\ &\gamma_{xy}=-\tfrac{1}{2}(s_2+s_{11}) \end{aligned}\right\} . \tag{26}$$

By comparing (25) and (26) we have

$$s_2=-r\,,\quad s_{11}=r\,, \tag{27}$$

although they give a finite value for γ_{yz}. For the deformation due to No. 4 and No. 8, it follows

$$s_4=r\,,\quad s_8=-r\,. \tag{28}$$

Although the results (23), (24) or (27), (28) give the finite values for γ_{yz}, γ_{zx} or γ_{yz} which do not conform with (21) or (25), the actual deformation of crystal did support the presence of these strain component.

§ 6. Calculation of Magnetic Anisotropy for Individual Cases and Comparison with Experiments

(1) (110) [001] rolling

By putting the values of s_i given in (20) into (8), we have for the anisotropy of long range order type (L.F. type)

$$E=\frac{1}{16}NlpS^2r(\alpha_1^2+\alpha_2^2+2\alpha_3^2)$$

$$=\frac{1}{16}NlpS^2r\alpha_3^2+\text{const.} \tag{29}$$

Similarly by putting (20) into (13), we have for short range order type (S.C. type)

$$E=\frac{1}{24}Nlp'\sigma r\alpha_1\alpha_2 \tag{30}$$

Eq. (29) (L.F. type) gives the anisotropy which makes x-y plane easy magnetizing *plane*, while (30) (S.C. type) gives the anisotropy which makes $[1\bar{1}0]$ easy magnetizing *direction*. Thus both anisotropies make $[1\bar{1}0]$ as stable direction which is in good agreement with experiments. The resultant anisotropy in (110) plane can be expressed by

$$E=\frac{1}{48}Nlr(3pS^2+p'\sigma)\cos^2\theta\,, \tag{31}$$

where θ is the angle between magnetization and roll direction. Since the coefficient K_u of the uniaxial anisotropy energy is defined by

$$E=-K_u\cos^2\theta\,, \tag{32}$$

we have

$$K_u=-\frac{1}{48}Nlr(3pS^2+p'\sigma)\,. \tag{33}$$

By comparing it with $K_u=-1.9\times10^5$ erg/cc at $r=0.5$ for slow cool specimen (Cf. Fig. 2), we have, by using the numerical value of Nl given in (5),

$$3pS^2+p'\sigma=5.9\%\,. \tag{34}$$

For perfect order specimen, since $K_u=-0.64\times10^5$ at $r=0.5$

$$3pS^2+p'\sigma=2.0\%\,. \tag{35}$$

(2) (001) [110] rolling

By putting (23) into (8), we have for L.F. type

$$E=\frac{1}{16}NlpS^2r(\alpha_1^2+\alpha_2^2+2\alpha_3^2+2\alpha_2\alpha_3+2\alpha_3\alpha_1)$$

$$=\frac{1}{16}NlpS^2r\,\alpha_3(2\alpha_1+2\alpha_2+\alpha_3)+\text{const.}\,, \tag{36}$$

and by putting (23) into (13), we have for S.C. type

$$E=\frac{1}{24}Nlp'\sigma r(\alpha_2\alpha_3+\alpha_3\alpha_1+\alpha_1\alpha_2)\,. \tag{37}$$

If we assume that s_4 and s_5 also take place together with s_1 and s_2 in the same region, the anisotropy becomes

$$E=\frac{1}{16}NlpS^2r\alpha_3^2 \tag{38}$$

for L.F. type and

$$E=\frac{1}{24}Nlp'\sigma r\alpha_1\alpha_2 \tag{39}$$

for S.C. type. Since the roll plane is $\alpha_3=0$, only S.C. type would be effective for this case. In actual case, however s_1 and s_2 take place in the upper half of the crystal as assumed in (23), so we must use (36) and (37) by taking into consideration of the crystal rotation.

As one will easily verify from Eq. (A. 2) in Appendix, the angle of the crystal rotation, ψ (the angle between [001] and normal of the plate), is given by

$$\psi=\sqrt{2}\,r\,. \tag{40}$$

Then the anisotropy in the rotated surface becomes

$$E=-\frac{\sqrt{2}}{8}NlpS^2r\psi\cos^2\theta$$

$$=-\frac{1}{4}NlpS^2r^2\cos^2\theta \tag{41}$$

for L.F. type and

$$E=\frac{1}{24}Nlp'\sigma r(1-\sqrt{2}\,\psi)\cos^2\theta$$

$$=\frac{1}{24}Nlp'\sigma r(1-2r)\cos^2\theta \tag{42}$$

for S.C. type. Thus the coefficient of uniax al anisotropy in the roll plane becomes

$$K_u=\frac{1}{24}Nl\{-p'\sigma r+2(p'\sigma+3pS^2)r^2\} \qquad (4$$

which is a quadratic function of r and ca be well fitted with the experimental curve a shown in Fig. 15. From this comparison w have

$$\left.\begin{aligned}pS^2&=0.36\%\\ p'\sigma&=0.78\%\end{aligned}\right\} \qquad (4$$

for slow cooled and

$$\left.\begin{aligned}pS^2&=0.50\%\\ p'\sigma&=0.54\%\end{aligned}\right\} \qquad ($$

for perfect order specimen.

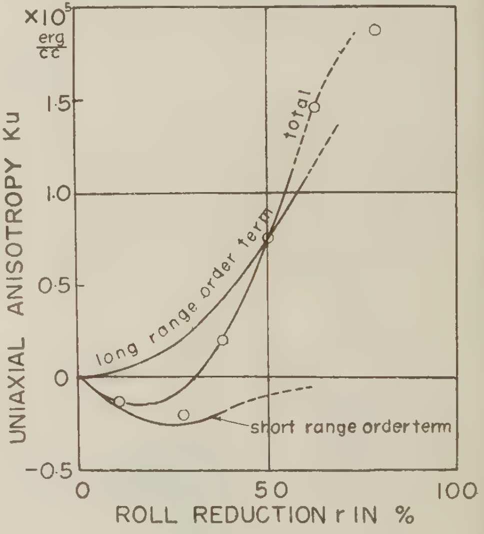

Fig. 15. Comparison of K_u-r curve for (001 [110] rolling between calculation and experiment. The experimental points are that fo previously slow-cooled specimen.

(3) (001) [100] rolling

By putting (27) into (8) we have

$$E=\frac{1}{8}NlpS^2r(\alpha_1^2+\alpha_3^2)$$

$$=-\frac{1}{8}NlpS^2r\alpha_2^2+\text{const.} \qquad (4$$

for L.F. type and by putting (27) into (13) w have

$$E=\frac{1}{24}Nlp'\sigma\alpha_2\alpha_3 \qquad (4$$

Roll direction is horizontal for all plates

for S.C. type. Since $\alpha_3=0$ in the roll plane (001), S.C. type (47) does not contribute to the torque. The L.F. type (46) makes [010] easy direction, being in good agreement with torque measurement. Since $K_u=-0.48\times10^5$ erg/cc at $r=0.52$, we have from (46)

$$pS^2=0.24\%. \tag{48}$$

Since easy direction of S.C. type anisotropy (47) is $[01\bar{1}]$, it would make the real easy direction to make a glancing angle with roll plane. This would be the reason why no clear domain was observed on the rolled surface. It should be expected that the crystal rotation in this case causes the rotation of $[01\bar{1}]$ towards the roll plane. Actually we can find the distorted uniaxial domains at the latter stage of rolling (Pl. 19).

§ 7. Discussion

As mentioned in § 6, principal points obtained by the experiments are well explained by the present interpretation. The values of pS^2 and $p'\sigma$ calculated for each case are summarized in Tab. IV. The fairly good agreement between different cases indicates the quantitative validity of the formulae. The order of magnitude of pS^2 or $p'\sigma$ may be also plausible, although we cannot make an exact estimation because of lack of informations about p or p'.

Table IV. Values of pS^2 and $p'\sigma$ calculated from the data for each rolling.

	(110) [001]	(001) [110]	(001) [100]
$3pS^2+p'\sigma$	5.9% (2.0)	1.8_6% (2.0_4)	—
pS^2	—	0.36 (0.50)	0.24
$p'\sigma$	—	1.6 (1.1)	—

It is interesting that the values of pS^2 and $p'\sigma$ for perfect order specimen are not so much different from that for slowly cooled specimen.* This is partly because that p_0 mentioned in § 4 (a) should decrease with an increase of S. Moreover it would be related to the fact that the manner of slips depends upon the degree of order[9),10),11)]. The fact that the anisotropy for a quenched specimen exhibits a large value (Cf. Fig. 2) would be also explained along the same line. It is interesting further that the anisotropy for polycrystal increases with a progress of order (Cf. Fig. 7), contrary to the case of single crystal. One possible explanation will be as follows: Since the individual crystallites in a polycrystal are surrounded by other crystallities, easy glide along one slip system should not be permitted. If several slip systems must contribute to the deformation at the same time, pairs of dislocations travelling along one slip system might be separated by another dislocation which belongs to the other slip systems. Then the separated dislocations would become effective in inducing the anisotropy. Thus the anisotropy would increase with a progress of order. If, however, order progresses to too much extent, the pairs of dislocations would become hard to be separated, resulting in an independent deformation for each crystallite which would lead to the break down at the crystal boundaries (Cf. Pl. 25).

Further detailed investigations on the roll anisotropy will offer the valuable informations about slip mechanism.

Acknowledgement

The authors are indebted to Prof. A. Ookawa for his full discussions about the problem of slip mechanism. This research was supported by the research grant of the Ministry of Education.

Appendix

Calculation of Crystal Rotation by Slip

Let us suppose that the face centered cubic crystal having the surface parallel to x-y plane is deformed by the slips which belong to the slip system having slip direction (d_1, d_2, d_3) and the normal of the slip plane (n_1, n_2, n_3). It can be shown by a simple calculation that the crystal surface rotates to the plane whose normal is

$$\left.\begin{aligned} p_1 &= -\sqrt{\frac{3}{2}}\,sn_1d_3 \\ p_2 &= -\sqrt{\frac{3}{2}}\,sn_2d_3 \\ p_3 &\doteqdot 1 \end{aligned}\right\} . \qquad \text{(A1)}$$

The angle of crystal rotation ψ, which is the angle between z axis and the normal (p_1, p_2, p_3), is given by

$$\psi = \sqrt{p_1{}^2+p_2{}^2} = \sqrt{\frac{3}{2}}\,sd_3\sqrt{n_1{}^2+n_2{}^2}\,. \qquad \text{(A2)}$$

The Component of Shearing Stress for Given Slip System

When the crystal is under the stress given by

$$\left.\begin{aligned} \sigma_{xx} &= T \\ \sigma_{yy} &= 0 \\ \sigma_{zz} &= -T \end{aligned}\right\} , \qquad \text{(A3)}$$

the shearing stress for given slip system whose slip direction is (d_1, d_2, d_3) and the normal of slip plane is (n_1, n_2, n_3), becomes

$$\tau = (d_1n_1 - d_3n_3)T\,. \qquad \text{(A4)}$$

Calculation for (001) [100] Rolling

The angle of crystal rotation caused by the slip No. 2 can be calculated by (A3), thus

---

* *Note added in proof*: The extremely slow development of anisotropy for perfect order (110) [001] specimen (Cf. Fig. 2) may be due to occurrence of easy glide.

$$\psi=\frac{|s_2|}{\sqrt{2}}\,. \qquad (A5)$$

By this rotation the component of the shearing stress should be changed by

$$\delta\tau=-\{2d_1n_3+d_2n_3+d_3(2n_1+n_2)\}\frac{\psi}{\sqrt{2}}\,. \qquad (A6)$$

Then it is easily found that

$$\frac{\delta\tau}{\tau}=+\frac{\psi}{2\sqrt{2}}>0 \quad \text{for No. 2 and No. 11}$$
$$=-\frac{\psi}{2\sqrt{2}}<0 \quad \text{for No. 4 and No. 8.} \qquad (A7)$$

Oscillations in Plasma I

By Shoji, KOJIMA, Kiyoe KATO and Shigeo HAGIWARA

Tokyo University of Education, Otsuka, Tokyo

(Received July 31, 1957)

By using super-regenerative detector plasma oscillations have been studied. On similar discharge tubes to Looney-Brown's tube many plasma oscillations were observed without auxiliary electron beams. When a small beam was introduced into main plasma, all the oscillations became stronger but their frequencies remain unchanged. For the excitation of plasma oscillations the existence of thick ion sheaths was not necessary. With usual discharge tubes plasma oscillations were detected from the outside of tubes by a small antenna. Many plasma oscillations having slight different frequencies were always observed. However, details of these oscillations are still obscure.

§ 1. Introduction

Ionized gases at low pressure are known to generate oscillations with frequencies of order of 1000 Mc. These oscillations are interpreted as the plasma-electron oscillation, whose frequency is expressed by

$$f_p=\sqrt{Ne^2/\pi m}\,, \qquad (1)$$

being N the electron concentration, e the charge and m the mass of electron.[1] Since the frequency is independent on the wave length, the group velocity of plasma waves should be zero. Recently Bohm and Gross took into account thermal motions of electrons and gave the following expression for th frequency:

$$f^2=f_p^2+(V_{th}/\lambda)^2 \qquad (2$$

where V_{th} is the mean velocity of electro and λ the wave length.[2] Then the grou velocity becomes $V_{th}^2/\lambda f$. Since λf is ord of the velocity of primary electrons, the grou velocity is usually very small. Therefore th each plasma oscillation is expected to be loca ized in a definite region of space. Such plasm oscillations had been cleary observed by Me rill and Webb[3]. By using a movable prob they showed that the oscillation with lar amplitude was detectable in a narrow region being near the layer where primary electrons received anomalous scattering. Merrill and Webb pointed out that the primary electrons were subject to velocity modulation when they passed throuth the oscillating layer of plasma and bunched subsequently at the region where the oscillations were detectable. Recent experiment by Bailey and Emeleus seems to confirm this interpretation[4]. In these experiments the oscillations were detected with a crystal rectifier.

With a super-heterodyne detecter and a specially designed discharge tube Looney and Brown[5] attempted to test the postulate of Bohm and Gross that plasma oscillations could be excited by a beam of electrons alone. However, they could not observe plasma oscillations except when large ion sheaths were introduced on the electrodes and a standing wave was set up in the region bounded by the sheaths.

The present experiments using more sensitive detecters have been undertaken to study of the effect of probe in Merrill and Webb's experiment and to study of the effect of ion sheaths in Looney and Brown's experiment.

§ 2. Apparatus

The coaxial cavity spectrometer which was discribed in a report on nuclear quadrupole resonances[6] was applied for the detection of plasma oscillations. The main part of the spectrometer is a two-cavity grid separation oscillator with a light-house tube 2C43. The block diagram of the detecting system is shown in Fig. 1. The oscillator works as a super-regenerative receiver when a quenching oscillater is applied or as a simple regenerative receiver without quenching oscillator. Frequency modulation was established by a vibrating metal sheet which was inserted into the plate cavity. The range of modulation could be extended upto 4 Mc, which was broader than the line widths of oscillations.

The super regenerative type has an advantage to be more sensitive than the simple regenerative type, but has a disadvantage that the quenching produces many sidebands spaced by its frequency. The quenching frequency adequate for the operation was about 1 Mc, which was smaller than the line width of oscillations. Therefore the super-regenerative type gave broadened line-shapes owing to the sidebands. The effect of sidebands, however, did not exceed several megacycles.

The frequency was measured by comparing with a overtone of a test oscillater of the frequency range between 30 and 500 Mc/s whose frequency was read acculately with a frequency meter.

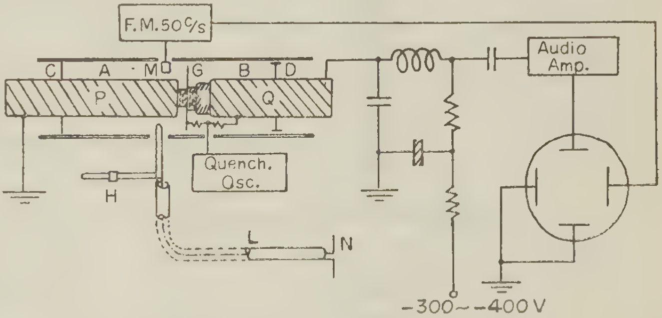

Fig. 1. Block diagram of detecting system.
A: Plate cavity, B: Cathode cavity, C: Plate plunger, D: Cathode plunger, G: Grid disk, H: Quarter wave trap, L: Coaxial cable, M: Modulation stub, N: Antenna, P: Plate cylinder, Q: Cathode cylinder, T: Light house tube (2C43).

Three types of discharge tubes containing mercury drops were employed. The type A was similar to descrived by Merrill and Webb. The type B was same as the type A except having no probes. The type C was simular to that described by Looney and Brown. The discharges were run in mercury vapour at a pressure of order of 10^{-3} mmHg.

§ 3. Results with the Discharge Tubes of the Type A

Diagram of a discharge tube of the type A is shown in Fig. 2. The cathode was a oxide coated type having a diameter of 5 mm and the anode a nickel disk having a diameter of 12 mm. The gap length was 16 mm. Movable double probes were used to pick up the oscillation and to measure the concentration and temperature of electrons, whereas a single probe was used by Merrill and Webb. The double probes consisted of two parallel tungsten wires of diameter 0.06 mm having a separation of 5 mm. Each probes were coated by glass except the both ends. By the courtesy of the double probes rather strong oscillations were picked up. So that the spectrometer was used as a simple regenerative receiver. An observed spectrum at the discharge current 26 mA and the room temperature 11°C is reproduced in Fig. 3. The center frequency of the plasma oscillation was 944.58±0.25 Mc and the half width was about 2 Mc. The center frequency was checked by the method of crystal detector and parallel wires resonator.

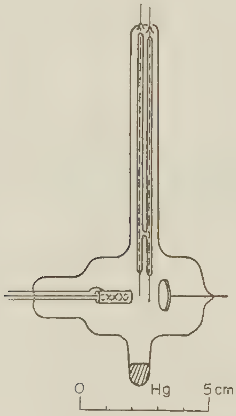

Fig. 2. Discharge tube of type A (Merrill-Webb's type)

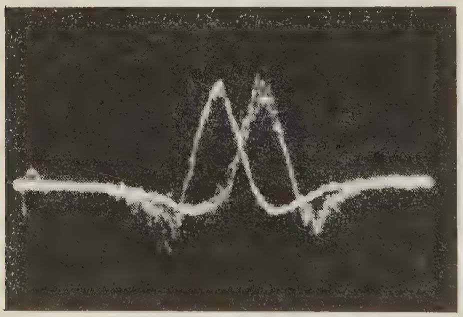

Fig. 3. An oscilloscope display of plasma oscillation with sinusoidal frequency modulation. The pattern is duplicated at increasing and decreasing sweeps of frequency.

The frequency of the oscillation changed linearly with discharge current. When the probes were moved parallel to the axis of tube, a slight change of frequency was observed. The maximum intensity of the oscillation occured in the middle region of discharge. Beside these strong oscillations many weak oscillations having different frequencies were simultaneously observed. Plots of thi observed frequencies against to the discharg currents are shown in Fig. 4. The plotes wer obtained by a series of measurements wher the oscillations were detected at a fixed fre quency of the receiver by changing the dis charge current. The plots were highly repro ducible. In order to determine the concen tration and temperature of eleclrons doubl probe charactors were measured. The squar of frequency of the oscillations were plotte against to the saturation current of the doubl probes which is proportional to the concen trating of electrons. The result is shown i Fig. 5. The linear relation accords qualita

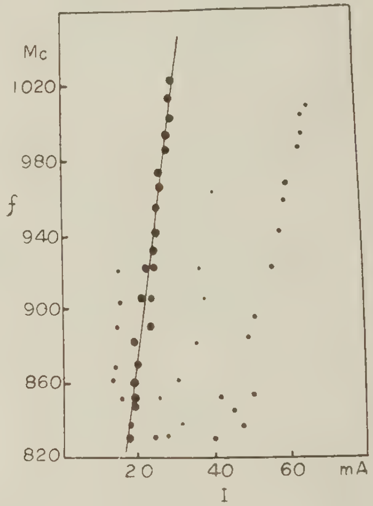

Fig. 4. Plots of frequencies of oscillations *vs* discharge currents on a tube of Merrill-Webb's type. Large circles indicate strong oscillations.

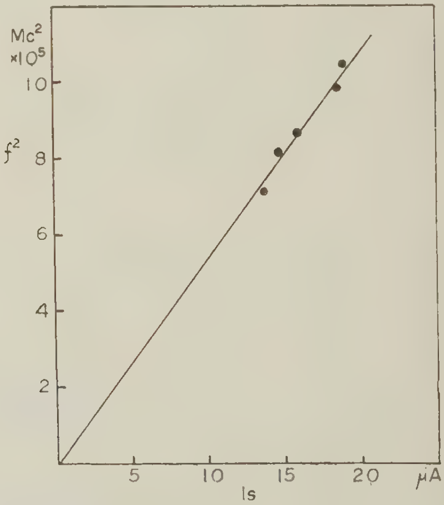

Fig. 5. Square of frequency *vs* saturation current.

tively with Eq. (1). The electron temperature obtained from the double probe measurement was about 18,500°K. Since the ion temperature was not obtained from the double probe measurement, it had to be assumed. Taking the ion temperature as 500°K the concentration of electrons, N, was evaluated as about 6×10^{10}. Eq. (1) gives 2200 Mc which is higher than observed frequency 938 Mc by facter 2.

§ 4. Results with the Tubes of Type B

Diagram of a discharge tube of the type B is shown in Fig. 6. The cathode was an oxide coated type 3 mm in diameter. The gap length and the diameter of the anode were same as the tubes of type A. The diameter of the glass envelope was somewhate larger than that of type A, but the total volume was smaller. The oscillations were detected with the super-regenerative receiver with the aid of a small antenna which was set outside of the discharge tube. Very weak plasma oscillations could be detected, and their frequencies were measured. The plots of frequencies against to the discharge current are reproduced in Fig. 7. In this case too, many oscillations were observed. At the condition that the electrodes were earthed with by-path condensors, the maximum intensity of oscillations was occured at the almost middle region of the gap. Therefore these oscillations did not arise from the anode current. When the antenna was moved away from the wall of the discharge tube, the intensity of oscillation was decreased approximately by the low of inverse square of distance. Since the plasma oscillation does not radiate transverse waves, the antenna would receive electrostatic induction of the oscillation. This experiment shows that for exciting plasma oscillations the existence of probes is not essential. The plots shown in Fig. 7 are qualitatively in accord with the result shown in Fig. 4. A series of oscillations in Fig. 4, however, were made strong by the existence of probes.

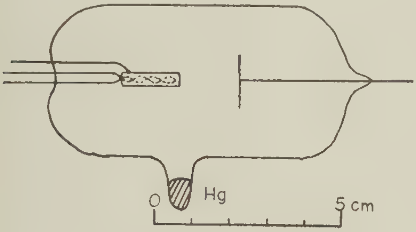

Fig. 6. Discharge tube of type B.

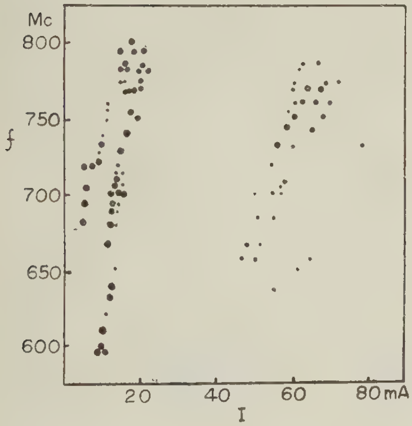

Fig. 7. Plots of frequencies of oscillations *vs* discharge currents on the tube having no probes.

§ 5. Results with the Tubes of Type C

Diagram of a tube of the type C is shown in Fig. 8. A pair of oxcide coated cathodes C_p's and a pair of ring anode W's produced main plasma. A cathod C_b, an accelerating anode A, an anode of the auxiliary discharge G, and an anode disk D formed a electron gun which provided auxiliary electron beams for exciting plasma oscillations. The oscillations were picked up with a movable single probe.

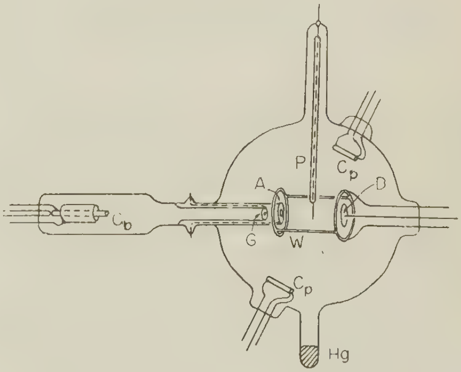

Fig. 8. Discharge tube of type C (Looney-Brown's type).
A: Accelerating electrode, C_p: Cathode for main discharge, C_b: Cathode for auxiliary discharge, D: Anode disk, G: Anode for auxiliary discharge, P: Probe, W: Ringe anode for main discharge.

(i) Without auxiary beams

In the present experiment plasma oscillations could be observed even when no auxiliary beam was introduced. These oscillations were probably excited by primary electrons which maintained the main plasma. The plots of frequencies of the oscillations against to the discharge currents are reproduced in Fig. 9.

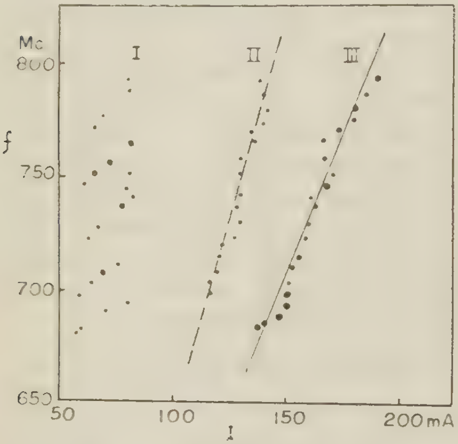

Fig. 9. Plots of frequencies of oscillations *vs* discharge currents on a tube of Looney-Brown's type.

From the plots the oscillations were classified into three groups as indicated in the figure. The first group appeared at discharge currents below 100 mA where the discharge showed visible change. Below this critical discharge current some of low frequency oscillations were often observed. The second and third group appeared above this critical discharge current. When receiver was kept at a fixed frequency, and the discharge current was changed, the second group appeared at lower discharg currents and the third group appeared at higher discharge currents. The oscillations of both groups were stable, whereas those of the first group were unstable.

For the all oscillations the efiect of ion sheaths was examined. The electrodes A and D were biased up to −200 V and thick ion sheaths were produced. However, any change of oscillations were not observed. On the other hand, when a thick ion sheath was produced on the probe, the oscillations belonging to the first and second groups became weaker, but not changed their frequencies. In this case too, the intensities of oscillations of the third group were almost constant.

By changing the position of probe the oscillations were studied. When the probe wa
moved slightly from the center of plasma t
a cathode C_p, the frequencies of oscillation
increased a little and the intensities change
The second group became stronger and th
third group became weaker. When the prob
was moved between the electrodes D and
the first group exhibited intensity maximu
at the central part and those of the secon
and third groups were almost constant throug
the region. The frequencies of the all osci
lations were slightly decreased as the prob
was apart from the center of the gap. B
using the prove and the electrode D as floa
ing double probe system the characteristi
curves were measured. The relation betwee
the square of frequency and the saturatio
current, which is proportional to the concent
ration of electrons, is shown in Fig. 10.

The oscillations of the third group are i
agreement with Eq. (1) qualitatively. There
fore these oscillations seem to correspond t
the oscillations indicated by solid line of Fig
4. The electron temperature determined fro
the double probe measurement was 27800°K
Assuming the ion temperature to be 500°K
the concentration of electrons was evaluate

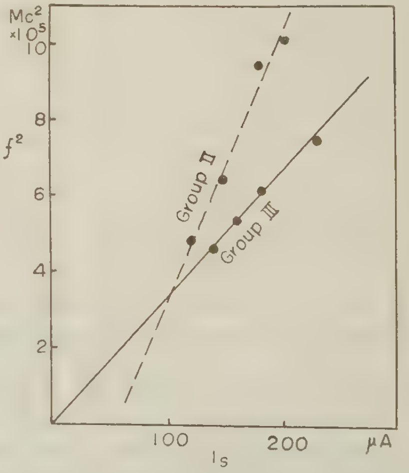

Fig. 10. Square of frequency *vs* saturation current.

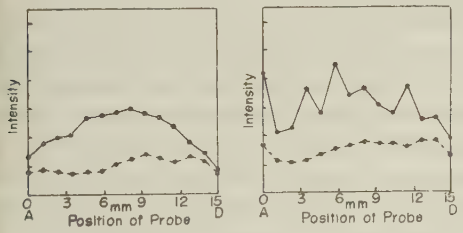
as 1.1×10^{11}. With these values Eq. (1) giv
2900 Mc which is higher than observed fre
quency 825 Mc by factor 3. Such descrepanc
ies were recently discussed by Esprester an
Hang[7]. Their interpretation, however, seem
to be not appricable for the localized plasm
oscillations. The present descrepancy probabl

comes from the error of probe measurements.

(ii) With auxiliary beams

An auxiliary electron beam of about 1.5 mA was introduced in the main plasma whose discharge current was between 50 mA and 200 mA. By the auxiliary beam all the oscillations became stronger, but their frequencies did not changed. The auxiliary beam of the present experiment was so small that the main plasma was not disturbed by it and much smaller than the case of Looney and Brown's experiment. Even when ion sheaths on the electrodes A and D were produced by applying a bias potential, oscillations were generally unchanged. When the ion sheaths were appropriate, some of the oscillations exhibited standing waves. Two examples of intensity distributions of the oscillations measured with the movable probe were shown in Fig. 11. One is the case presenting no standing waves and the other case presenting standing waves. For comparisons, the intensity distributions, where the auxiliary beam was absent were also shown by dotted lines in the figure.



(a) $\begin{cases} f=850\text{ Mc} \\ I=183\text{ mA} \end{cases}$ (b) $\begin{cases} f=740\text{ Mc} \\ I=180\text{ mA} \end{cases}$

Fig. 11. Intensity distribution.

§6. Conclusion

(1) Plasma oscillations were detected from the outside of a discharge tube. It was shown that probes were not essential for the oscillations.

(2) Without the aid of remarkable ion sheaths plasma oscillations were excited.

(3) Frequencies of plasma oscillations were independent to the beam of electrons. Intensities of the oscillations were increased by the beam.

These results suport Bohm and Gross's theory.

(4) Many plasma oscillations having slight different frequencies were detected. However, details of the oscillations are still obscure.

The authors are grateful to Dr. T. Ichimiya of the Electrical Communication Laboratory for continuous interest and for making available to obtain the discharge tubes. The authors are also grateful to Dr. K. Takayama for helpful discussion. This work was financed by the Scientific Research Fund of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 11, NOVEMBER, 1957

On the Phototubes Sensitive to the Wide Spectral Region

By Masao SUGAWARA

Hitachi Central Research Lab. Kokubunji-machi, Kitatamagun, Tokyo

(Received July 20, 1957)

Phototubes sensitive to light in the spectral region from ultraviolet to near infrared were made. It is revealed that these phototubes are suitable for the spectral photometry throughout the spectral region above mentioned.

The light transmission and photoelectric yields of the thin photocathode films such as antimony-caesium, silver-caesiumoxide and bismuth-caesiumoxide were investigated.

§1. Introduction

In, 1938, Goerlich[1] has made a phototube which has a comparatively uniform response to light in the visible spectral region. In this tube, an antimony-caesium or bismuthcaesium film of appropriate thickness is evaporated on a silver-caesiumoxide surface. It is expected that we may have a phototube with the similar character, too, if a half of the inner wall is covered with a semi-transparent antimony-caesium photosurface, and the other half of the wall with an ordinary silver-caesiumoxide photosurface.

If the spectral yields of phototubes prepared in these methodes are comparable to those of the ordinary silver-caesiumoxide phototubes in the reddish spectral region and to those of the antimony-caesium phototubes in the bluish one, they are very useful for spectral photometers, especially for those of self-recording type.

In the phototubes firstly prepared by Goerlich, a certain amount of incident light is absorbed by the upper layer, and the remainder stimulates the underlying photosensitive layer. Photoelectrons generated there have to pass through the upper layer to escape into vacuum.

Thus, it is important to control the thickness and the structure of the upper layer. In this method, however, it is not easy to control them since the interaction between two layers is unavoidable.

In the phototubes prepared in the second method, the photoelectrons can escape into vacuum directly from the photosurface. Of course, the tube characteristics are affected by the thickness of the semi-transparent photosurface. In this second method, however, it can be measured through the optical transmission.

In this point of view, the second method i adopted to prepare a phototube sensitive t the light in a wide spectral region. The co bination of antimony-caesium and silver-caes umoxide photosurfaces (Sb-Ag type), and tha of bismuth-caesiumoxide and silver-caesium oxide (Bi-Ag type) are mainly investigated.

When the semi-transparent photosurface i made of the antimony or bismuth film of th thickness of about 2.0 μg per cm^2, the photo tubes are obtained, which have satisfactoril high responses for spectral photometry in th spectral region from $\lambda 400$ mμ to $\lambda 800$ mμ.

The appropriate thickness of antimony o bismuth film above mentioned was determine by the preliminary experiments in which th light transmission and photoelectric yields o the photosurfaces of various thickness wer measured in the spectral region from $\lambda 400$ m to $\lambda 800$ mμ. Futhermore, from these result some considerations on the structures of photosurfaces and the sources of photoelectric emission are made.

§2. Light Transmissions and Photoelectri Yields of Thin Photosurfaces

(1) *Experimental procedure*

A schematic diagram of the experimenta tube is shown in Fig. 1. A small piece o metal 2 mg in weight are evaporated on th glass plate "b" by resistive heating of tungsten coil "f". The distance between "f and "b" is 10 mm. As a source of caesium a nickel capsule "l" containing a mixture o caesiumchromate and silicon powder is use The tube is sealed onto the pumping syste in such a position that the glass plate lies horizontally, looking down the evaporator. The shield plate "j" slides down on the tube wall to keep clear the portion of the inner wall from metal evaporation. The metal is wholly evaporated in a vacuum of the order of 10^{-7} mm Hg. The average rate of evaporation is estimated at about 0.2 mg per minute. The thickness of the evaporated film is calculated by the geometrical arrangement of the evaporator and the glass plate.

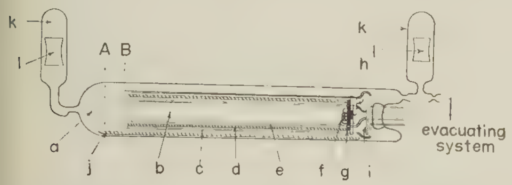

Fig. 1. Schematic diagram of experimental tube a, glass envelope; b, glass plate; c, Ni support; d, Al evaporated; e, anode; f, *W* small helical coil; g, aquadac film; h, cathode lead; i, mica plate; j, movable Ni plate shield; k, side tube; l, caesium source; AB, reference part in transmission measurements.

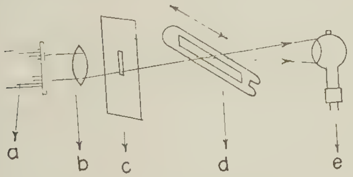

Fig. 2. Arrangements for transmission measurements a, monochrometer; b, lens; c, aperture; d, experimental tube: e, phototube.

In the cases of bismuth and silver, the film formed on the glass plate "b" is oxidized to some extents. Caesium is liberated in the side tubes by eddy current heating. The tube, together with the side tubes, is then sealed off from the vacuum system. The light transmission in this stage is measured. Then the sensitization with caesium is done by heating the whole system of tube at 100°~110°C in a thermostatt. The transmission and photoelectric yields of these tubes are measured in both cases of the light of λ380~λ800 mμ is incident on the glass and photosurface sides of the cathods.

The arrangement of apparatus used in the transmission measurment is diagramatically shown in Fig. 2. The incident light is focused to a rectangle of 8×0.5 mm on the photocathode surface. The transmission is defined as the ratio of the light intensity passed throgh the glass envelope, photosurface and glass plate to that through only the glass envelope, or the light transmitted through the portion of the tube indicated by AB in Fig. 1. The monochrometer and the photocurrent amplifier used in these measurements are the same as described in the previous paper.[2] The photoelectric measurement is also made in the same arrangement, applying the voltage to the experimental tubes. To simplify the process of experiment, the slit of the monochrometer is maintained at a constant width of 0.08 mm. The relative energy distribution in this case of the monochrometer, measured with a thermopile, is shown in Fig. 3.

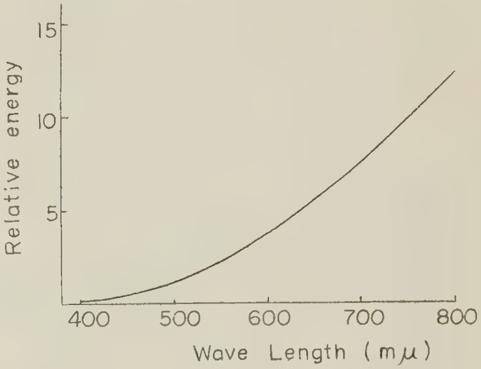

Fig. 3. Energy distribution of light from the monochrometer with a constant slit width.

In this paper, transmission and the photoelectric yields is plotted against the thickness of initially evaporated metal film expressed in the unit of μg per cm², for it is very difficult to measure accurately the thickness of such a photosurface which has a very complicated structure.

(2) *Results of experiments*

In antimony film, a distinct boundary line is observable at the thickness of about 10 μg per cm², the thinner portion being coloured blownish, while the thicker portion greyish.[3] The obtained results of the transmission of the antimony film are shown as dotted curves in Fig. 4. The appearance of the antimony-caesium photosurface is different from that of antimony itself. In the portion thicker than 40 μg per cm², the interference fringes appear, instead of a distinct boundary. In Fig 4, the transmission of the antimony-caesium film for the light of shorter wave length decreases logarithmically with the film thickness, while that for longer wave length varies periodically. Similar results are also obtained by Wallis.[4]

In Figs. 5 and 6, the photoelectric yields of the antimony-caesium photosurfaces are plotted against the film thickness. In case of th light incident on the glass side, the curve ha a peak at about 2 μg per cm² thick. (Fig. 5) In case of light incident on the photosurfac side, the yield is almost constant in the portio thicker than 6~8 μg per cm² (Fig. 6). How ever, in both cases the photoelectric yield falls abruptly at about 1.0 μg per cm² thic as shown by chain lines, and the fluctuatio of the photocurrent is observed. But wher a glass plate covered with a transparent conductive film, neither abrupt change nor fluctuation of the photocurrent is observed.

—— usual case ···· excess caesium case.

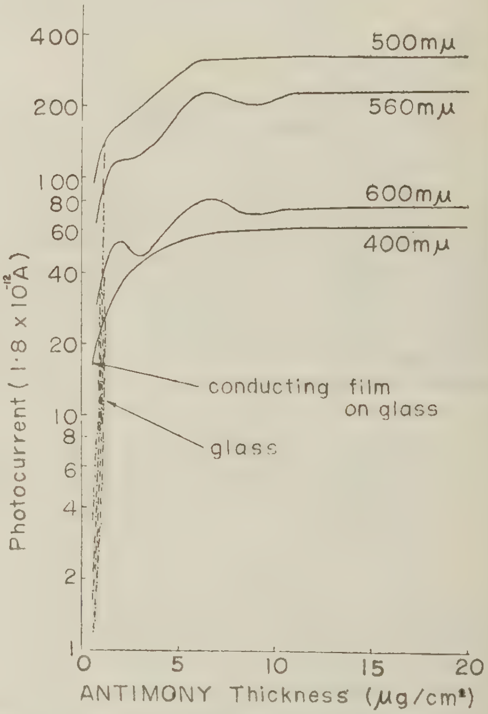

Fig. 6. Photoelectric yields of the antimony-caesium film for the light incident on the photosurface side.

Dotted curves in Fig. 5 are obtained when the caesium more than usual is evoporated into the experimental tube. It is interesting that the curve for λ600 mμ is higher than that obtained in usual case.

In Fig. 7, the transmission of silver film for the light of λ600 mμ is shown. Dotte curves "a" and "b" correspond to that befor and after the oxidation, and the solid curves to the completed silver-caesiumoxide film, re spectively. The transmission increases in ac companying with the progress of oxidatio of silver, and decreases as the silver caesium-oxide film is formed.

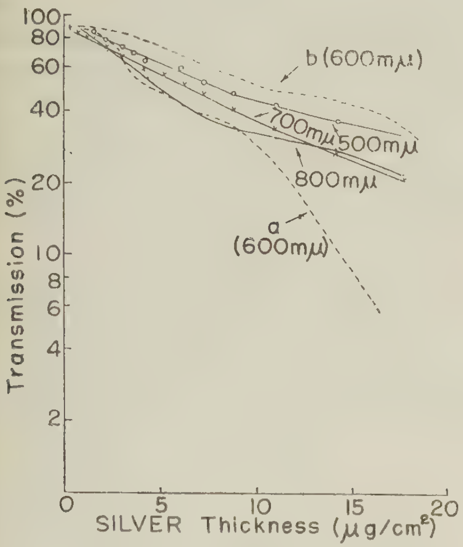

Fig. 7. Transmission of silver and silver-caesium-oxide films.
a, silver film (for λ600 mμ); b, after oxidation (for λ600 mμ); solid curves, silver-caesiumoxide fiilm.

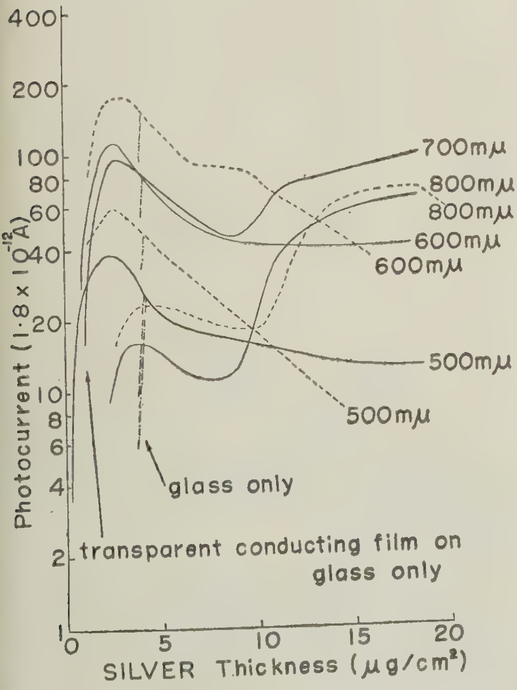

Fig. 8. Photoelectric yields of the silver-caesium-oxide film.
—— light incident on the photosurface side:
.... light incident on the glass side.

In Fig. 8 the photoelectric yields of silver-caesiumoxide film are plotted against the film thickness. The yield decreases abruptly at the thickness of about 4 μg per cm² as shown by chain lines. In the portion thinner than this critical thickness, the photocurrent fluctuate similarly just as in case of antimony-caesium.

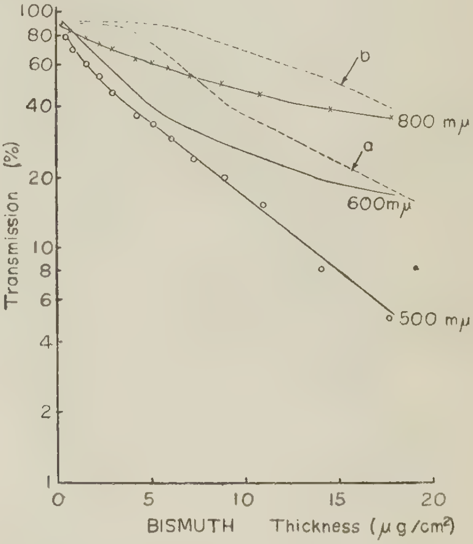

Fig. 9. Transmission of bismuth and bismuth-caesiumoxide films.
a, bismuth film (for λ600 mμ)
b, after oxidation (for λ600 mμ)
solid curves, bismuth-caesiumoxide film.

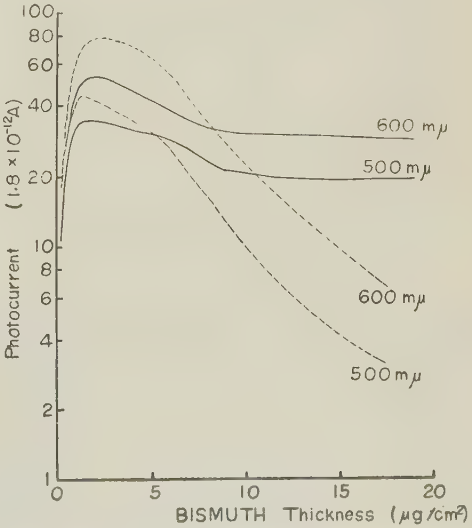

Fig. 10. Photoelectric yields of bismuth-caesium-oxide films.
—— light incident on the photosurface side;
.... light incident on the glass side.

In the thicker portion, the yields decreases with the film thickness for the light of shorter wave length, while for the longer wave length light it begins to increase steeply at the thickness of about 9 μg per cm^2.

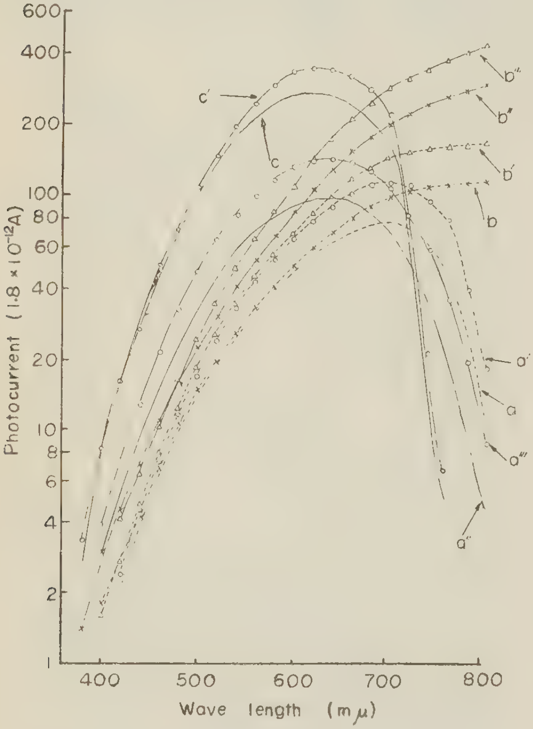

Fig. 11. Spectral responses of semi-transparent photosurfaces.
a, silver-caesiumoxide, 6 μg per cm^2 thick, before silver re-evaporation, light incident on the photosurface side; *a'*, ditto, light incident on the glass side; *a''*, after silver re-evaporation, light incident on the photosurface side; *a'''*, ditto, light incident on the glass side; *b*, *b'*, *b''*, *b'''*; silver-caesiumoxide, 12 μg per cm^2 thick, refering respectively as above; c, bismuth-caesiumoxide, light incident on the photosurface side; c', ditto, light incident on the glass side.

When a transparent conducting film was formed previously on the glass plate, the yield, having a maximum at about 2 μg per cm^2, does not show any abrupt change and fluctuation. In this case also, the yield for the light of λ800 mμ is small in the thinner portion. Dotted curves " a " and " b " in Fig. 9 represent the transmissions of the bismuth film before and after the oxidation, respectively. In Fig. 10, the yields of the bismuth caesiumoxide photosurface are plotted against the film thickness. The variation of the yield with the film thickness is similar to that of th silver-caesiumoxide photosurface.

In Fig. 11, the spectral response of sem transparent silver-caesiumoxide photosurfac and that of semi-transparent bismuth-caesium oxide one are shown. The sensitization b re-evaporation of silver as already Asao[5] ha developed is also made. The yield of a thi ner silver-caesiumoxide photosurface for th red and the infrared region is also small eve after the silver re-evaporation.

§ 3. The Phototubes Responsible for Wid Regions of Spectra

From the results described in the precee ing section, it is infered that antimony-caesium

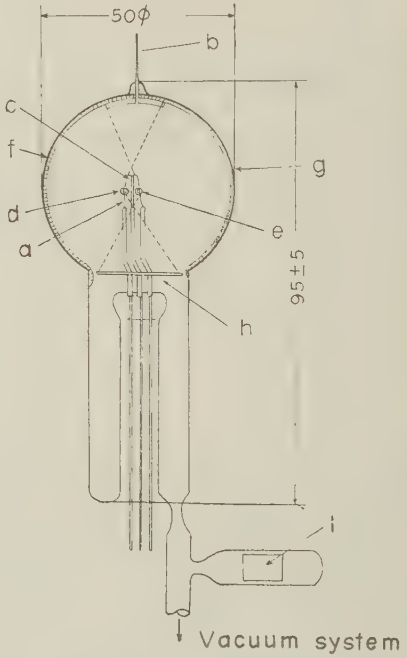

Fig. 12. Schematic view of the tube construction a, anode; b, cathode lead; c, Ni plate; d, silve head; e, antimony bead; f, silver-caesiumoxid photosurface; g, semi-transparent antimony caesium photosurface; h, mica plate; i, caesiur source.

or bismuth-caesiumoxide photosurface, n silver-coesiumoxide one, should be used as semi-transparent photosurface. For, the la is not sensitive to the reddish light in th thinner portion.

The schematic view of the phototube no prepared is shown in Fig. 12. Small amoun of antimony (or bismuth) and of silver a mounted separately in tungsten helical coils situated both sides of nickel circular plate of 8 mm in diameter. An ordinary silver-caesium-oxide photosurface is formed on a nearly half of the inner wall of the globe, while on a remaining half, a semi-transparent antimony-caesium (or bismuth-caesium) film are formed respectively. By measuring the light transmission, the evaporated amount and consequently, the film thickness is controled. The typical examples of the spectral yields of the Sb-Ag type phototubes prepared in this manner and those of ordinary phototubes are shown in Fig. 13, and those of Bi-Ag type phototubes in Fig. 14. It has been confirmed that phototubes having a response such as "a" and "a′" in Fig. 13 are suitable for spectral photometry in the spectral region from λ400 mμ to λ800 mμ. The curve "a′" is more uniform than curve "a", with the high yield in the range between λ600 mμ to λ700 mμ. This is considered to be due to the excess of caesium. But the more excess caesium does not give a better result, lowering the yield over all the spectral region. Curves "b" and "c" in Fig. 13 correspond to the spectral response when the antimony film is too thin and too thick respectively. The response shown in Fig. 14 is superior in its uniformity, but inferior in the yield, especially in the ultraviolet region, to the curves "a" and "a′" in Fig. 13.

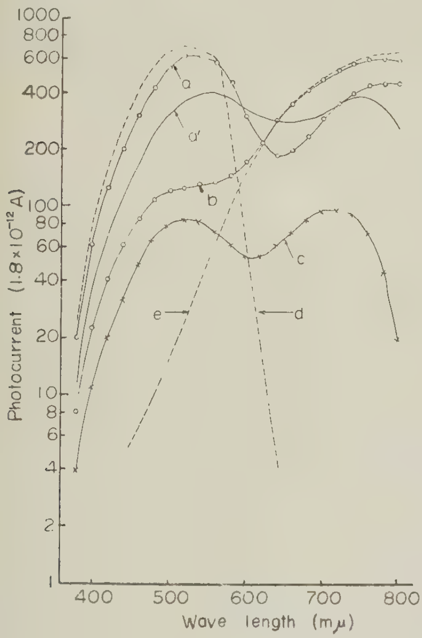

Fig. 13. Spectral yield variation due to the thickness of semi-transparent antimony-caesium photosurface.
a, appropriate thickness and moderate caesium; a′, appropriate thickness and excess caesium; b, thinner thickness; c, thicker thickness; d, antimony-caesium phototube (30 μA/lumen); e, silver-caesiumoxide phototube (30 μA/lumen).

In Fig. 15, the relation between the photocurrent and the flux of incident light are shown in the case of the Sb-Ag type phototubes. In this figure it is noticeable that the proportionality of the photocurrent to the illuminating light flux is well satisfied in the range less than 10^{-9} A. Any abnormal effects such as time lag described in the previous paper[9)] are not observed.

The deviation from proportionality in curves "A" and "B" is due, as Widmaier and Engstrom[6)] have pointed out, to the high resistivity of the semi-stransparent antimony-caesium film. When the inner surface of the glass globe is covered with a transparent conductive film, the proportionality holds in the photocurrent range larger than 10^{-9} A. as shown by "C" and "C′" in Fig. 15.

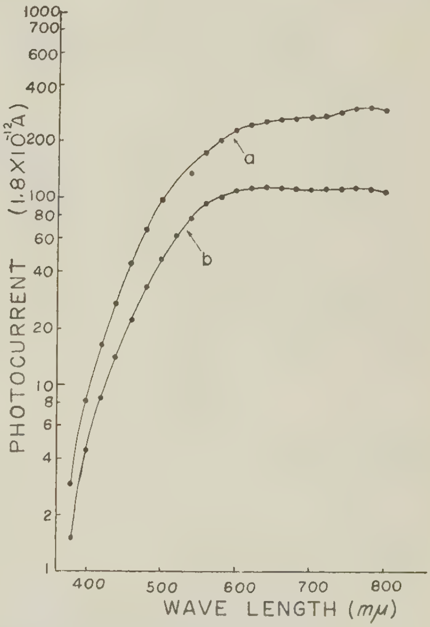

Fig. 14. Spectral yield variation due to the thickness of semi-transparent bismuth-caesiumoxide photosurface.
a, moderate thickness; b, thicker thickness.

In Fig. 16, current-voltage curves for light of various wave length are shown. The hump at about 15 volts is due to the secondary electrons produced by the photoelectrons which return to the cathode. Such discontinuities, as reported by Gordon-Smith[11] and also by Taylor[8] are not observed. The phototubes of Bi-Ag type also have the similar characteristics with those of Sb-Ag type.

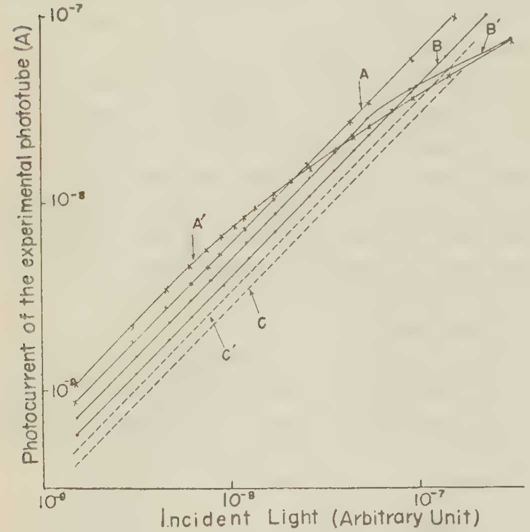

Fig. 15. Current-incident light curves of the Sb-Ag type phototubes.
A, phototube No. 1, for λ720 mμ; A', for λ520 mμ;
B, phototube No. 2, for λ720 mμ; B', for λ520 mμ;
C, phototube No. 3, for λ720 mμ: C', for λ520 mμ.

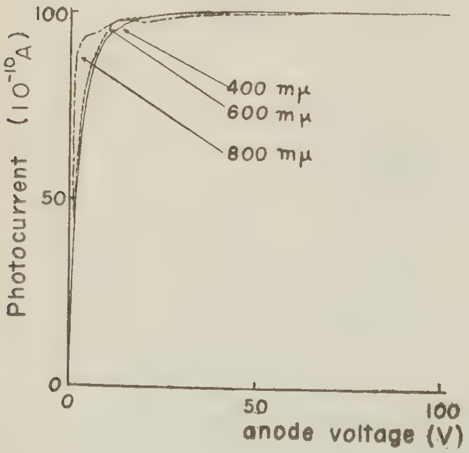

Fig. 16. Current-voltage curves of the Sb-Ag type phototube.

After all it can be concluded that the phototubes now prepared have the characteristics suitabe for spectral photometry in the region from λ400 mμ to λ800 mμ. If the envelope is made of fused silica instead of glass, thes
phototubes are used in the spectral regio
from λ200 mμ to λ1000 mμ.

§ 4. Some Considerations on the Thin Photo cathode

According to Hammer,[9] when the lig
with wave length λ passes through no
absorbing film on a glass plate, transmissio
maxima and minima arise at the thickness
satisfying the following conditions;

$$nd=(2\,\mathrm{m}+1)\,\frac{\lambda}{4}\,,\quad \text{for minima}$$

$$nd=(2\,\mathrm{m}+2)\,\frac{\lambda}{4}\,,\quad \text{for maxima}\quad \mathrm{m}=0,1,2,\cdot\cdot$$

where n is the refractive index of the mediu
and d, the thickness. According to Wallis,
n of antimony-caesium film for the light o
λ800 mμ is 1.8. Considering the antimony
caesium film as a non-absorbing film for th
longer wave length light, the thicknesses co
responding to the maxima and minimum
the upper most curve (for λ800 mμ) in Fig.
are calculated to be $d=110$ and 330 mμ fo
minima, and $d=220$ mμ for maximum, an
these coincide well with those obtained b
Wallis. By comparing these values with th
corresponding thickness of initially evaporate
antimony film of 6.5, 19, 13 μg per cm^2, re
spectively, it is known that the thickness o
antimony film increases to 11 times of th
initial value after it turns into the antimony
caesium film. Using this factor 11, the ab
sorption coefficient of antimony-caesium fo
the light of λ400 mμ is determined as 11×10
cm^{-1} from Fig. 4. This is somewhat large
than Wallis' value 4×10^5 cm^{-1} for the lig
of 404 m, and Burton's[10] 4.7×10^5 cm^{-1} for th
ultraviolet light. But the difference is tole
able as the reflection is not taken into ac
count in our case. It is well known that th
films of silver, antimony and bismuth ar
composed of separate aggregates. As the fil
thickness increases, the separate aggreate
grow in size and merge into together.[3] A
the results, the discontinuous change in th
resistivity, photoemission and other propertie
occurs. In antimony-caesium film this chang
takes place at about 10 μg per cm^2 thic
while in the antimony-caesium film at abou
1 μg per cm^2 thick, the ratio is 10. This
in a good agreement with the value 11 calc

lated from the transmission measurement.

Mayer and Nossek[11)] measured the variation of the photoelectric yield with film thickness for potassium. The yield was independent on the film thickness in the portion thicker than 3∼4 atom layers. From this fact, they concluded that the photoelectric effect of the potassium is the surface effect. In Fig. 6, the yield of the antimony-caesium is almost constant in the portion thicker then 6∼8 μg per cm^2 (90∼120 mμ).

This result seems to show that, for antimony-caesium, the volume photoelectric effect is concerned.

As to the effect of excess caesium for the antimony-caesium yield in Fig. 5 and 13, it is presumed that the atoms of caesium in excess migrate into the Cs_3Sb film and form the emission sources which are rather sensitive for the light of longer wave length.

The variation of curves for the light incident on the photosurface side in Figs. 8 and 11 are explained as follows. In the thinner portion, by oxidation and reaction with caesium, the silver or bismuth aggregates grow in size. The obtained photosurface in this portion is coarse-grained, accompanying with the irregularities of the film lattice which are greatest at some thickness. The photoelectrons are generated chiefly in these irregular portion of lattice and the maximum of the yield appears.

In the thicker portion, the film is composed of a continuous layer and the variation of the photoelectric surface with film thickness is not so large as in the thinner portion. So the photoelectric yield changes more gradually with the film thickness in the portion thicker than about 10 μg per cm^2 in Figs. 8 and 11.

The steep rise of the yield for the longer wave length light at the thickness of 9 μg per cm^2 in Fig. 8 is due to the silver layer underlying the caesimoxide layer. It is presumed that the active centers of photoelectrons for the longer wave length are formed mainly on the intricated boundaries between silver and caesiumoxide.

The large absorption coefficient of antimony-cresium for the shorter wave length light in Fig. 4 is due to lattice absorption.[4)10)] The transmission of the silver-caesium and bismuth-caesiumoxide in Figs. 7 and 9 decreases with film thickness more gradually than those of antimony-caesium above mentioned. This means that the absorption of light in the former two is small and may not be thought as lattice absorption. This is in agreement with above considerations as to the sources of photoelectrons.

The photoelectric yield for the light incident on the glass side is mainly dependent on the depth where the photoelectrons are generated, but in the silver-caesiumoxide and bismuth-caesiumoxide, it seems to be affected also by the film structure.

Summary

The light transmission and the photoelectric yield of the antimony-caesium, bismuth-caesiumoxide and silver-caesiumoxide photosurface of various thickness were measured in the spectral region from λ400 mμ to λ800 mμ. Applying these results, the photoelectric tubes which are highly sensitive to the light in the wide spectral region were prepared. These tubes can be satisfactorily used in the spectral photometry. It is concluded that the yield variation with thickness is caused by the change in film structure.

The writer wishes to express his gratitude to Dr. Hamada, Dr. Tadano, Dr. Nakamura, Messrs Kiuchi and Makino for their kind guidance throughout this work. He also wishes to thank Messrs. Takei, Fukushi, Kobayashi, Miss Kumasaka and Miss Saito for their helpful assistance.

A Study on the Attenuation of Shock Waves due to Obstacles in the Passage

By Ryuma KAWAMURA and Haruo KAWADA

Institute of Science and Technology, University of Tokyo

(Received June 14, 1957)

Results are reported of a shock-tube experiment on the retardation of shock waves due to obstacles in the passage. A one-dimensional analysis is applied on the flow field resulting from the interaction of shocks and obstacles, and a theoretical relation between the attenuation of shocks and the resistance of the passage is derived. The drag coefficients of a series of simple bluff obstacles used in the experiment are estimated. Comparisons with available steady-flow data are made along with some discussions.

§ 1. Introduction

It has been recognized that a plane shock front is highly stable as it propagates through a stagnant gas in a uniform channel. Thus, when it hits an obstacle placed in the passage, the propagating front gets once curved as it is transmitted beyond but restores the plane shape in a short distance of travel downstream which we shall call "the formation distance."

On the other hand, with the advent of the shock front an unsteady flow is induced around the obstacle accompanied by a complicated system of waves produced by multiple reflections and interactions. But these waves decay rapidly and the flow reaches a steady state after a short time interval. In the course of these processes, flow separation (for bluff obstacles) and/or choking (for large-blockage ones) are considered to occur.

The shock front transmitted past the obstacle is weaker than the incident one and is retarded with respect to the latter. The flow field suffers momentum loss due to the resistance of the obstacle in the unsteady and steady stages. Apparently the retardation of the shock must balance with this momentum loss, and especially, the attenuation in the ultimate state with the steady-flow resistance of the obstacle. This condition will be form lated in the next section on the basis of on dimensional wave theory.

It was intended in the present experiment investigate the effect of simple bluff obstacl on the attenuation of weak plane shocks p duced in a shock tube and also to check t analytical theory to be developed in the ne section.

The interaction of a plane shock wave w simple-shaped obstacles has been treated fr a different angle, i.e. as the diffraction p blem, by various authors, experimentally w shock tubes4) as well as theoretically. these studies, attentions are given to t two-dimentional flow field behind the sho wave as it passes over the surface of t body. On the other hand, the interaction a shock with wire screens or porous pla placed normally in the passage has recen been investigated experimentally by seve researchers.1)2)6) This problem is essentia the same with the present one, and the resu obtained are parallel. The present one m be regarded as a microscopic model of t phenomenon. The attenuation of a shock p pagating through an empty channel is a rat old problem and has already been studied every detail. The attenuation is evidently caused by the wave system generated by the growth of wall boundary layers, and must balance with the momentum loss due to the wall friction. Some theories have been presented with reasonable experimental verifications.[3)]

§ 2. Theory

Sufficiently long after the incidence of the shock front on the obstacle, as stated above, a steady flow is established around it. The transmitted shock front is situated far downstream and is plane and uniform. The reflection of the incident shock at the fore surface of the obstacle forms an upstream-propagating shock front. It is then plane and uniform, too. Thus the flow field in the ultimate state is as shown in Fig. 1 (a), where S_R and S_T denote, respectively, the reflected and transmitted shocks, and C the contact layer consisting of the particles passed by the waves during the transient stage. The flow regions (I), (II) and (IV) are those of uniform states behind the incident, transmitted and reflected shocks, respectively, and (0) is the region of rest. (III) is the region downstream of the obstacle and is regarded as uniform.

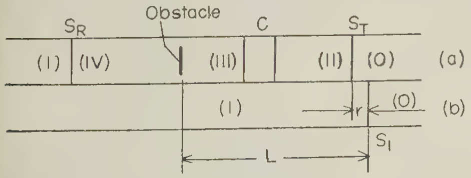

Fig. 1. Idealized model of flow field.
(a) Obstacle present, (b) Obstacle absent.

In the absence of the obstacle, the flow field at the same instant consists, as in Fig. 1 (b), merely of two uniform regions (I) and (0) separated by the undisturbed incident shock S_I.

The regions (IV) and (III) are connected by the steady flow past the obstacle. The obstacle exerts resistance D on the flow. Let us denote density, flow velocity, pressure and specific enthalpy with ρ, u, p and H, respectively. ($H=3.5\,p/\rho$ for air.) Let the physical quantities of the regions (0), (I). (II), (III), and (IV) be designated with subscripts 0, 1, 2, 3 and 4, respectively. The conservation laws of mass, momentum and energy can be expressed as follows:

$$\rho_4 u_4=\rho_3 u_3, \tag{1}$$

$$p_4+\rho_4 u_4^2=p_3+\rho_3 u_3^2+D/A\,, \tag{2}$$

$$u_4^2/2+H_4=u_3^2/2+H_3\,, \tag{3}$$

where A is the cross-sectional area of the channel.

Pressure and velocity are invariant through the contact layer, i.e. $p_3=p_2$ and $u_3=u_2$. So the above equations are transformed into the following forms including only quantities of (IV) and (II):

$$p_4+\rho_4 u_4^2=p_2+\rho_4 u_4 u_2+D/A\,, \tag{4}$$

$$\rho_4 u_4^3+7p_4 u_4=\rho_4 u_4 u_2^2+7p_2 u_2\,. \tag{5}$$

Now let all the physical quantities be made non-dimensional by dividing them with those in the region (0). (For the case of velocity u we make it non-dimensional by dividing with the speed of sound in (0), a_0.) Thus

$$\tilde{p}_i\equiv p_i/p_0,\quad \tilde{\rho}_i\equiv \rho_i/\rho_0,\quad \tilde{u}_i\equiv u_i/a_0\,,\cdots.$$

We get from Eqs. (4) and (5)

$$\tilde{p}_4+1.4\tilde{\rho}_4\tilde{u}_4^2=\tilde{p}_2+1.4\tilde{\rho}_4\tilde{u}_4\tilde{u}_2+1.4\tilde{D}\,, \tag{6}$$

$$\tilde{\rho}_4\tilde{u}_4^3+5\tilde{p}_4\tilde{u}_4=\tilde{\rho}_4\tilde{u}_4\tilde{u}_2^2+5\tilde{p}_2\tilde{u}_2\,, \tag{7}$$

where $\tilde{D}\equiv D/(\rho_0 a_0^2 A)$.

Next, let us denote the pressure ratio across a shock with the shock Mach number M with $P(M)$, the density ratio with $R(M)$, and the velocity behind it divided by the speed of sound ahead of it with $U(M)$. M is the ratio of the propagation speed of the shock to the speed of sound ahead of it, and is a parameter representing the shock strength. Let the shock Mach number of S_I, S_R and S_T be M_I, M_R and M_T. Moreover, abbreviations such as P_R, R_R, P_T, etc. are used here for $P(M_R)$, $R(M_R)$, $P(M_T)$, etc. It follows from the definitions that

$$\tilde{p}_4=P_R P_I,\quad \tilde{\rho}_4=R_R R_I,\quad \tilde{u}_4=U_I-U_R A_I\,,$$
$$\tilde{p}_2=P_D\,,\quad \tilde{u}_2=U_D\,,$$

and Eq. (6) and (7) are rewritten in the following forms:

$$F_1(M_R,M_T;M_I)=\tilde{D}: \tag{8}$$

$$P_R P_I+1.4R_R R_I(U_I-U_R A_I)^2$$
$$=P_D+1.4R_R R_I(U_I-U_R A_I)U_D+1.4\tilde{D}\,,$$

$$F_2(M_R,M_T;M_I)=0: \tag{9}$$

$$R_R R_I(U_I-U_R A_I)^3+5P_R P_I(U_I-U_R A_I)$$
$$=R_R R_I(U_I-U_R A_I)U_D^2+5P_D U_D$$

Eliminating M_R from (8) and (9), we get a relation between M_T and $\tilde{D}$ as

$$F_3(M_T;\, M_I)=D\,, \qquad (10)$$

which, in practice, can only be solved by graphical calculations for fixed values of M_I. Now, define "the attenuation rate" of the shock, m, by

$$m=(M_I-M_T)/M_I\,,$$

and the drag coefficient of the obstacle referred to the cross-sectional area of the tube, C_D, by

$$C_D=D/(1/2\cdot\rho_4 u_4^2 A)\,.$$

Then Eq. (10) can be reduced to the form:

$$F(m, C_D;\, M_I)=0\,. \qquad (11)$$

This relation between m and C_D was calculated for the strengths of the incident shock $\xi=0.6$, 0.5 and 0.4 ($M_I=1.25$, 1.36 and 1.51, respectively), where ξ is the reciprocal of the shock pressure ratio, i.e. the ratio of the pressure ahead of the shock to that behind it. The result of the calculation is shown in Fig. 2.

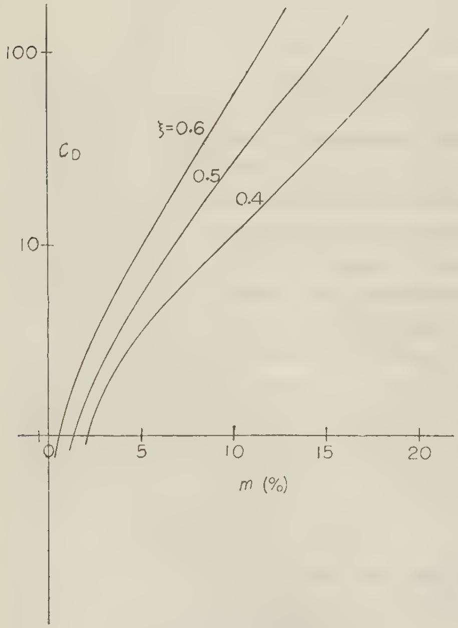

Fig. 2. Relation between m and C_D.

The transcendental equations (8) and (9) are reduced to linear ones in the limiting case where the blockage ratio of the obstacle, $b=B/A$, is either very small or very near to unity, B being the blockage area of the obstacle.

(i) The case $b\ll 1$:

S_R is slightly stronger than a sound wave, and S_T slightly weaker than the incident shock Put

$$M_R=1+\varepsilon_1 \qquad (12)$$

$$M_T=M_I(1-\varepsilon_2)\,. \qquad (13)$$

Further, we may put $C_D=C_{D0}\times b$, wher C_{D0} is the free-stream drag coefficient of th obstacle. Second- and higher-order terms o ε_i being neglected in Eq. (8) and (9), w obtain linear equations for ε_1 and ε_2, and thence, the following numerical results:

ξ	0.6	0.5	0.4
$\varepsilon_1/C_{D0}b$	0.033	0.076	0.182
$\varepsilon_2/C_{D0}b$	0.0125	0.0196	0.0290

(14)

(ii) The case $1-b\ll 1$:

In this case the flow is considered to b always choked. S_R is slightly weaker tha the normal reflection of the incident shock, i.e

$$M_R=M_N-\varepsilon_1\,, \qquad (15)$$

and S_T slightly stronger than a sound wave i.e.

$$M_T=1+\varepsilon_2\,, \qquad (16)$$

where M_N is determined by M_I and is some what smaller than the latter. The flow Mac number in the region (IV), M_4, is decided b assuming the isentropic contraction of th flow from (IV) to the throat section wit a contraction ratio (1–b). Thus

$$(U_I-U_R A_I)/A_R A_I=M_4=M_{cr}(b)$$

Putting the expressions (15) for M into th above equation and neglecting higher-orde terms of ε_i, we obtain the following results

ξ	0.6	0.5	0.4
$\varepsilon_1/(1-b)$	0.45	0.49	0.64

(17)

Then from Eq. (9) ε_2 is calculated as

ξ	0.6	0.5	0.4
$\varepsilon_2/(1-b)$	2.16	3.20	4.96

(17′)

§ 3. Experiment

The experiment was performed by the us of a shock tube with a 5 cm×15 cm cross section.[6] A test chamber of 60 cm in lengt is situated about 3 cm downstream of the dia phragm station. A 50 cm×15 cm glass obser vation window presents a wide field of view convenient for schlieren photography employed in the experiment.

A 5 mm-thick brass plate was inserted horizontally in the test-chamber dividing it into the upper and lower channels, which are 10 cm and 4.5 cm, respectively, in heights. The obstacles were set at the upstream end of the upper channel, while nothing was placed in the lower channel. Thus the disturbed transmitted and undisturbed incident schocks could be observed simultaneously, and the retardation lengths measured directly from the photographs.

9. Camera
10. To pressure gauge
11. To vacuum pump

The high-pressure chamber was kept at atmospheric pressure and the low-pressure channel was evacuated with a 1 HP vacuum pump to an appropriate pressure, by which the strength of the incident shock was regulated. The shock strength used in the experiment was between 0.6 and 0.4 in terms of ξ, the reciprocal of pressure ratio.

For schlieren photography use was made of two kinds of spark light sources. The one is an ordinary 15 KV single-shot unit, and the other is a newly-designed 8 KV "multiflash" unit capable of giving several shots at a repetitive frequency of about 5 KC.⁷⁾ A photo-screen was set through the glass window at the upstream end of the lower channel, and the incident shocks were picked up with a photo-multiplier, the output signal of which triggered the spark light source through thyratron relays and a pulse-delay circuit. Wave-speed measurements were not made for individual snapshots, and the shock strengths were calculated from the initial pressure ratios across the diaphragm according to the previous calibrations. The schlieren axis was set in most cases at 40 cm to 45 cm downstream of the obstacle position. The field of view was 15 cm to 25 cm in diameter. Some photographs were also taken in the field 10 cm to 20 cm downstream in order to observe the formation process of plane fronts.

Table I. List of obstacles.

No.	size
	(Circular cylinders)
1	40 mm
2	58 mm
3	25 mm × 3 (row)
	(Normal plates)
4	40 mm
5	58 mm
6	29 mm × 2 (row)
7	14.5 mm × 4 (row)
8	25 mm × 3 (row)
9	30 mm × 3 (row)
	(Semi-circular shells)
10	40 mm
11	58 mm

Normal flat plates, circular cylinders and semi-circular shells of various sizes were adopted as obstacles either singly, or, to diminish the formation distance, in combination into grids. They are tabulated in Table I. Let us denote, for simplicity, the shapes of obstacles with s; $s=1$, 2, and 3 are to correspond, respectively, to circular cylinders, normal flat plates, and semi-circular shells, In order to produce measurable retardations of shocks within the test-chamber length, obstacles with fairly large blockage ratios, amounting at minimum to 40%, had to be used in the experiment.

Table II. Measured values of retardation rates r/L (%).

No.	s	b(%)	L(cm)	0.6	0.5	0.4
1	1	40	50		1.5	
2	1	58	50	3.2	3.7	4.4
3	1	75	45	5.4	7.5	9.5
4	2	40	35–40	2.4	2.9	
5	2	58	40–45	5.8	6.1	7.3
6	2	58	30–45	4.2	5.3	
7	2	58	30–45	3.0	3.8	
8	2	75	45	7.2	10.0	11.0
9	2	90	30–45	10.9	13.9	17.6
10	3	30	30–45		4.0	
11	3	58	30–40		7.9	

(5)

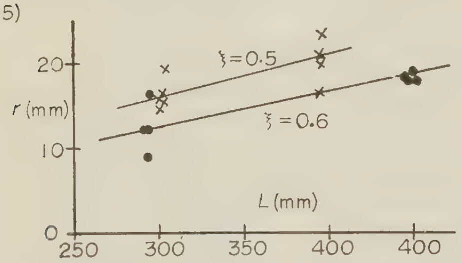

Fig. 5. Example of original data of r. No. 6-obstacle.

(6)

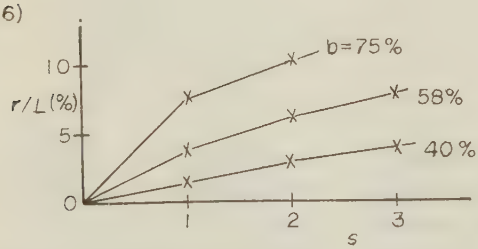

Fig. 6. Experimental result: r/L versus s. $\xi=0.5$.

In the field of view more than 30 cm downstream of the obstacle, where most photographs were taken, transmitted shock fronts were apparently plane and normal in any case. Only when the obstacle was single, were observed a pair of thin oblique wave fronts attached behind the main front. From each schlieren record the streamwise coordinate of the incident shock L measured from the obstacle center and the retardation distance of the transmitted shock with respect to th incident one, r, were obtained. The orde of magnitude of r's was a few to severa centimeters, and they were determined with a accuracy of 0.5 mm which was the thicknes of shock fronts appearing on the photograph The observed values of r's showed a fairl large scatter (see Fig. 5). For every (s, b, ξ combination the average value of r/L w determind. They were surprisingly small to large values of b, and even for $b=90\%$ t transmitted shocks were much stronger th sound waves. (See Table II and Figs. 6 to

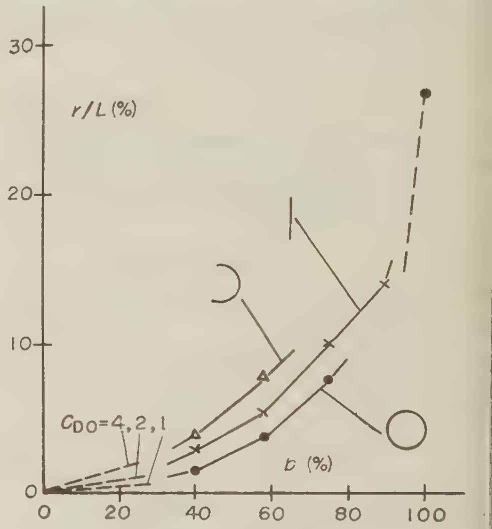

Fig. 7. Experimental result: r/L versus b. ξ=0.5
(Broken lines: theory, (12)~(17))

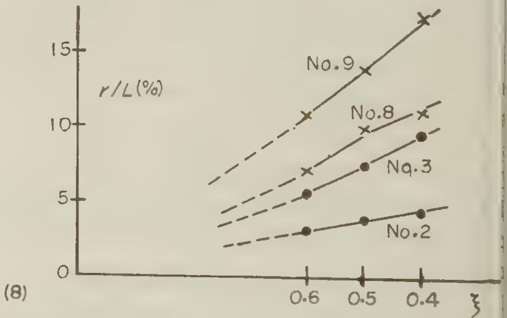

Fig. 8. Experimental result: r/L versus ξ.

At 10 cm to 20 cm downstream of the o stacle the transmitted shock fronts were pe ceptively curved and the accompanying wa systems appeared fairly thick, indicating t transient flattening process in progress ther Let us call the foot of the transmitted fro B and its belly C as in Fig. 9, and denote t retardation distances of B and C with respe to the incident shock with r_1 and r_2. They are plotted versus L in Fig. 10 for a 58%-blockage single normal-plate obstacle. (r_2-r_1), the thickness of the curved front, is also plotted in Fig. 11. In most part of the 10 cm field of view (r_2-r_1) is positive so that the shock front is convex to the up-stream, but it decreases with distance and near $L=200$ cm changes its sign. The thickness (defined as positive when the front is convex towards the upstream) thus appears to undergo a damped oscillation around zero till finally a plane and normal front is established.

Nos. 5, 6, and 7 obstacles have similar shapes and same blockage ratio. If scale effects or wall effects on the flow are absent, the retadation data for them are expected to lie on a single curve when plotted in terms of r/B_1 versus L/B_1, where B_1 denotes the channel height for a single obstacle and the mesh length of the grid for a multiple one. As shown in Fig. 12, No. 5 and No. 6-data appear to continuate smoothly but No. 7 data lie considerably lower than the extension of the other two sets. The reason is not yet clear. Typical schlieren photographs are presented in Plates 1 to 4.

§4. Analysis and Discussions

Sufficiently far downstream of the obstacle, that is for L much larger than the channel height, the retardation rate of the shock, r/L, may be equated with the attenuation rate in shock Mach number, $m=(M_I-M_T)/M_I$. When L is not so large, some correction is necessary, depending on the formation character of the plane front behind the obstacle. The simplest form of the correction may be: $(r-r_0)/L=m$. r_0 in this equation was estimated to be 3 mm or so for the 58%-blockage single normal plate. This quantity will be halved for a double obstacle. The systematic evaluation of the necessary correction is difficult and was not made. It is assumed here to be small, and we put $r/L=m$. Then, from Eq. 11 (Fig. 2) and Table II, C_D can be calculated for various (s, b, ξ)-combinations. C_D may be somewhat overestimated here because of the negligence of the corrections.

It is noticeable that C_D changes only little with ξ in the present experimental range. For example, $C_D=11.0$, 12.0, and 9.8, respectively, for $\xi=0.6$, 0.5, and 0.4 for No. 3-obstacle. A variation of ξ for fixed s and b corresponds to variations of Mach and Reynolds numbers of the incoming flow. The

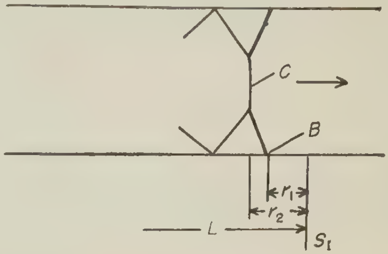

Fig. 9. Transmitted shock front near the obstacle.

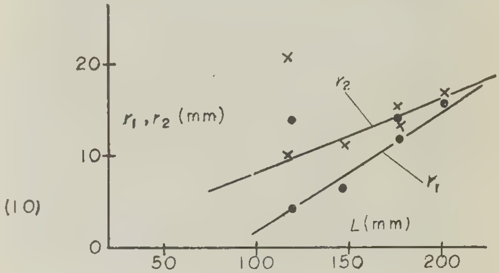

Fig. 10. Experimental result: r_1, r_2 versus L. No. 5-obstacle.

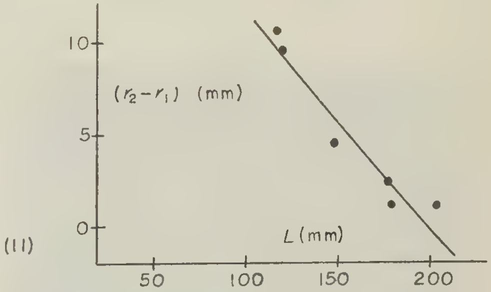

Fig. 11. Experimental result: (r_2-r_1) versus L. No. 5-obstacle.

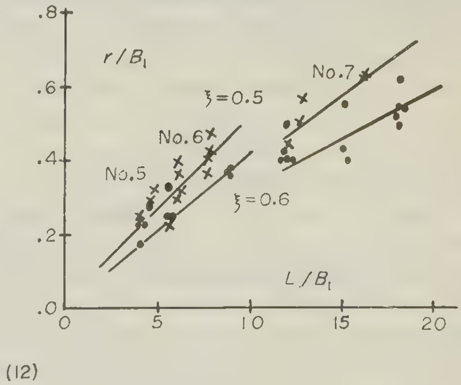

Fig. 12. Experimental result: r/B_1 versus L/B_1. Nos. 5- to 7-obstacles.

above-mentioned result shows that the drag coefficients of the bluff bodies which we adopted as obstacles are insensitive to Mach and Reynolds numbers, and is in accordance with ordinary experimental facts.

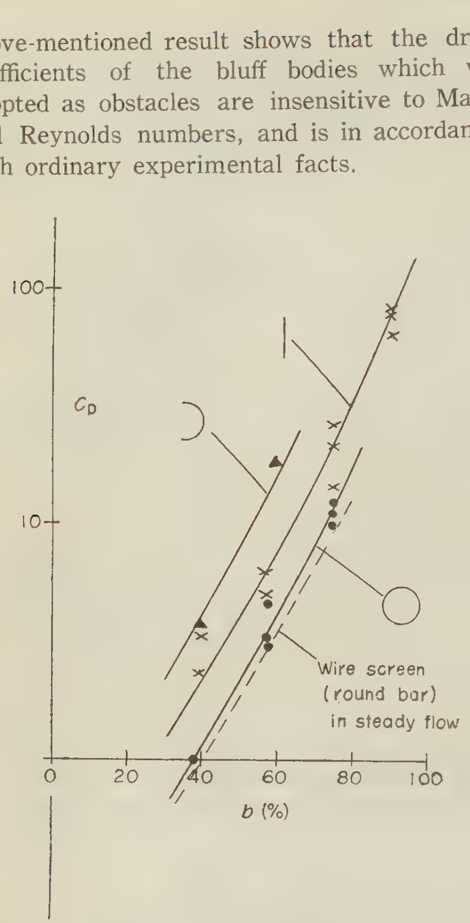

Fig. 13. Relation between estimated C_D and b. (Data for $\xi=0.6$, 0.5 and 0.4 compiled.)

C_D increases with b exponentially (Fig. 13). Steady-flow data of the drag coefficients of such large-blockage obstacles are not available, but the above result may be compared with the low-speed pressure-drop-coefficient data (which are practically equal to C_D) of wire screens. The dependence of C_D on b is similar for both, and the order of magnitude agrees reasonably.

A few critical remarks may be necessary here. In the first place, the presence of the walls and the large blockage ratio of the adopted obstacles modified the steady flow to a considerable extent. For example, the total pressures in front of and behind the obstacle were very different, and in about half of the cases the flow is considered to have been choked. Secondly, the flow field past the obstacle was always limited in the upstream and downstream by the reflected shock front and the contact layer, respectively, contrary to an ordinary steady flow. Lastly, although the obstacles were two-dimensional in shape, their span-to-diameter ratios were not sufficiently large, and some three-dimensional effects may have been caused. However, in the present experiment, the insensitivity of the separation-point locations of the bluff obstacles to the flow character and the smallness of the viscosity effects in the short-duration flow are considered to have prevented such troubles.

Next, a consideration must be given on the mechanism of the retardation and attenuation of the shock. It is diffracted as it passes the obstacle, being retarded and disfigured, and then, by the action of the reflected-wave system catching over it, converges to the original plane shape. If a steady potential flow were to be established around the obstacle in the ultimate state, the shock front would eventually acquire the original strength (attenuation being absent), since there would be no steady resistance. But there would be an amount of retardation corresponding to the momentum loss due to the transient-stage resistance of the obstacle, which is caused by the assymmetric pressure distribution on the fore- and rear-half surface. In the real flow, separation takes place on the surface of the obstacle, giving rise to a certain pressure resistance even in the ultimate state. The separated flow generates a wave system, which catches over and weakens the transmitted front, the ultimate attenuation of which must balance with the steady-state resistance. Such a wave system is superposed on the regular row of the reflected waves, but is not visible contrary to the latter.

The phenomenon treated here is a complicated one which is essentially instationary, and, unlike ordinary shock diffraction phenomena, involves viscosity. There exists no theory to describe the phenomenon completely. For the full understanding of it, the unsteady flow character around the bluff body in the shock tube must be investigated in detail.

In this experiment large scatters of data made the result somewhat unsatisfactory along with the uncertainty in the photographic measurements of small quantities. If stronger shocks are used with similar arrangements, greater retardations will be realized. However, the steady flow will be always choked and the retardation effects of wall friction will not be negligible.

§ 5. Conclusions

The retardations and attenuations of weak shocks due to various simple-shaped obstacles placed in the passage have been measured by use of a shock tube and instantaneous schlieren photography. The formation process of plane shock fronts behind the obstacles have also been investigated in some detail. On the theoretical side, a method of estimating the drag of the obstacle from the attenuation of the shock has been developed on an assumption of a simple quasi-steady flow model. Using the experimental data of the shock retardations, the drag values of a series of obstacles have been calculated. They show reasonable agreements with available steady-flow results.

An Approximate Solution of the Hypersonic Laminar Boundary-Layer Equations and its Application

By Tosimitu NAGAKURA and Humio NARUSE

Department of Physics, Faculty of Science,
Tokyo Metropolitan University

(Received July 31, 1957)

Approximate formulae of the displacement thickness and the skin friction of the hypersonic laminar boundary layer are derived by use of von Kármán's integral method, assuming the heat-insulated wall, the Prandtl number of unity and Chapman and Rubesin's formula for the variation of viscosity with temperature. The results obtained are compared with some exact solutions. Because of the good agreement, it seems that these formulae are very useful.

These formulae, together with the tangent-wedge-approximation, are applied to the viscous flow over slender bodies with a sufficiently sharp leading edge. As an example, the pressure distribution over a flat plate is calculated numerically over the entire region of the surface. Comparison with other author's theoretical results as well as experimental values is made.

§ 1. Introduction

In the hypersonic flow the laminar boundary layer is rather thick because of high temperatures in this region, and its thickness increases like M^2 for a given Reynolds number on the assumption of Chapman and Rubesin's formula for the variation of viscosity with temperature. The outward deflection of the streamline induced by this thick boundary layer causes a significant increase of the pressure in the main flow and this induced pressure in turn feeds back into the boundary layer and affects its rate of growth, and thus so-called shock-wave-boundary-layer interaction occurs.

Recently many works concerning this interaction have been published. For instance several theoretical studies on these problems for a flat plate or a wedge with an infinitely sharp leading edge have been made by Bertram⁽¹⁾, Kuo⁽²⁾, Lees⁽³⁾, Lees and Probstein⁽⁴⁾, Li and Nagamatsu⁽⁵⁾, Maslen⁽⁶⁾, Pai and Shen⁽⁷⁾, Shen⁽⁸⁾, and Stewartson⁽⁹⁾, and a few experimental studies by Bertram⁽¹⁰⁾, Hammitt and Bogdonoff⁽¹¹⁾, and Kendall⁽¹²⁾.

From these studies we may expect that the hypersonic viscous flow over slender bodies with a sufficiently sharp leading edge can be separated in two regions, namely the usual boundary layer and the inviscid layer of small disturbance, and that Prandtl's boundary layer equations remain valid even in the presence of interaction as long as $(\delta/x)^2 \ll 1$.

In these interaction problems the displacement thickness of the boundary layer plays a particularly important role, since it represents an effective thickening of the body. Therefore it is desirable to have an approximate formula of the displacement thickness when the pressure distributions on the body surface are prescribed.

In this paper these formulae, together with those of the skin-friction, are derived by approximating the velocity profile by a polynomial of degree four of the Howarth normal distance, as in the usual von Kármán-Pohlhausen approach, and comparison with a few exact solutions is made.

Further these formulae, together with the tangent-wedge-approximation, are applied to the viscous flow over slender bodies with a sufficiently sharp leading edge, and then it is shown that the solution over the entire region of the surface can be obtained numerically and especially the inverse problem can be solved easily. Lastly, the pressure distribution over a flat plate is calculated numerically and comparison with other author's results as well as with Kendall's experimental values is made.

§2. Basic Equations

The equations of the two-dimensional compressible boundary layer are as follows.

$$(\partial/\partial x)(\rho u)+(\partial/\partial y)(\rho v)=0\ , \tag{2.1}$$

$$\rho u(\partial u/\partial x)+\rho v(\partial u/\partial y) = -dp/dx+(\partial/\partial y)\{\mu(\partial u/\partial y)\}\ , \tag{2.2}$$

$$\partial p/\partial y=0\ , \tag{2.3}$$

$$\rho u(\partial/\partial x)(C_pT)+\rho v(\partial/\partial y)(C_pT)=u(dp/dx) +(\partial/\partial y)\{(\mu C_p/\sigma)\partial T/\partial y\}+\mu(\partial u/\partial y)^2\ , \tag{2.4}$$

$$p=R\rho T\ , \tag{2.5}$$

where $(x,\ y)$ are the distances along and normal to the surface, $(u,\ v)$ the velocity components in the $(x,\ y)$ directions, p, ρ, T the pressure, the density, the absolute temperature at $(x,\ y)$ respectively, C_p the specific heat at constant pressure, σ the Prandtl number, and R is the gas constant referred to unit mass.

Integrating (2.1) and (2.2) across the boundary layer and combining the results we have the familiar momentum integral equation, which can be written as

$$\frac{\mu_w}{\rho_\infty u_\infty{}^2}\left(\frac{\partial u}{\partial y}\right)_w=\frac{d}{dx}\left[\frac{\rho_1u_1{}^2}{\rho_\infty u_\infty{}^2}\int_0^\delta\frac{\rho u}{\rho_1u_1}\left(1-\frac{u}{u_1}\right)dy\right] -\frac{p_\infty}{\rho_\infty u_\infty{}^2}\left[\frac{d}{dx}\left(\frac{p_1}{p_\infty}\right)\right]\int_0^\delta\left(1-\frac{\rho u}{\rho_1u_1}\right)dy\ , \tag{2.6}$$

where μ is the coefficient of viscosity, δ the boundary layer thickness, and the suffixes w, 1, ∞, 0 denote respectively the corresponding values at the surface of the body, at the outer edge of the boundary layer, at infinity upstream and at the stagnation point.

If we write

$$\left.\begin{aligned} &y/\delta=\eta\ ,\\ &-(\delta^2/\mu_wu_1)\,dp_1/dx=\Lambda\ ,\\ &\frac{\gamma-1}{2}M_1{}^2\int_0^1\frac{\rho u}{\rho_1u_1}\left(1-\frac{u}{u_1}\right)d\eta=Q(\Lambda)\ ,\\ &\int_0^1\left(1-\frac{\rho u}{\rho_1u_1}\right)d\eta=\delta^*/\delta=1-\lambda(\Lambda)\ , \end{aligned}\right\} \tag{2.7}$$

where δ^* is the displacement thickness of the boundary layer, γ the ratio of specific heats and M the Mach number, and we expand u/u_1 in power series of η as follows:

$$u/u_1=a(\Lambda)\eta+b(\Lambda)\eta^2+O(\eta^3)\ , \tag{2.8}$$

we have from (2.6), (2.7) and (2.8)

$$\frac{d}{dx}\left(\frac{p_1}{p_\infty}Q\delta\right)-\frac{\gamma-1}{2\gamma}\,\delta(1-\lambda)\,\frac{d}{dx}\left(\frac{p_1}{p_\infty}\right) =\mu_wu_1\frac{(\gamma-1)M_\infty{}^2}{2\rho_\infty u_\infty{}^2}\frac{a}{\delta}\ . \tag{2.9}$$

Using (2.7), this can be transformed into

$$\frac{d}{dx}\delta^2+2\frac{p_\infty}{p_1}\frac{d}{dx}\left(\frac{p_1}{p_\infty}\right)\delta^2+\frac{2}{Q}\frac{dQ}{dx}\delta^2 =\mu_wu_1\frac{(\gamma-1)M_\infty{}^2}{\rho_\infty u_\infty{}^2}\frac{p_\infty}{p_1}\left[\frac{a(\Lambda)-\{1-\lambda(\Lambda)\}\Lambda}{Q(\Lambda)}\right]. \tag{2.10}$$

In the next section (Figs. 1, 2) we shall show that the three functions $a(\Lambda)$, $\lambda(\Lambda)$, $Q(\Lambda)$ approximately satisfy the following relations:

$$[a(\Lambda)-\{1-\lambda(\Lambda)\}\Lambda]/Q(\Lambda)=A+B\Lambda\ , \tag{2.11}$$

$$a(\Lambda)=a_1+b_1\Lambda\ , \tag{2.12}$$

where A, B, a_1, b_1 are constants. By using these relations, we can get two different formulae for δ as follows.

Case I. If we substitute (2.11) in (2.10) and put

$$\left.\begin{aligned} &2+(\gamma-1)B/\gamma=\alpha\ ,\\ &(\gamma-1)A\mu_wu_1\,M_\infty{}^2/\rho_\infty u_\infty{}^2=K\ , \end{aligned}\right\} \tag{2.13}$$

then α is constant and we can obtain from (2.10) and (2.7) the relation:

$$\frac{d}{dx}\delta^2+\alpha\frac{p_\infty}{p_1}\frac{d}{dx}\left(\frac{p_1}{p_\infty}\right)\delta^2+\frac{2}{Q}\frac{dQ}{dx}\delta^2=K\frac{p_\infty}{p_1}\ . \tag{2.14}$$

This can be integrated to give

$$\delta^2=\left(\frac{p_1}{p_\infty}\right)^{-\alpha}Q^{-2}\left\{\int_{x_0}^x KQ^2\left(\frac{p_1}{p_\infty}\right)^{\alpha-1}dx+\text{const.}\right\}. \tag{2.15}$$

We shall discuss the functional form of $Q(\Lambda)$ in the next section.

Case II. If we substitute (2.12) in (2.10) and put

$$\left.\begin{aligned} &2-\{(\gamma-1)(1-\lambda-b_1)/\gamma Q\}=\alpha\ , \\ &a_1(\gamma-1)M_\infty{}^2\mu_w u_1/\rho_\infty u_\infty{}^2 Q=K\ , \end{aligned}\right\} \tag{2.16}$$

we can obtain again (2.14) and (2.15) as in Case I. Here α is assumed to be constant and its justification will be given in the next section.

On the other hand the skin-friction at the wall, τ_w, is given by the equation:

$$\tau_w=\mu_w(\partial u/\partial y)_w=u_1\mu_w a(\Lambda)/\delta\ , \tag{2.17}$$

where the relations (2.7) and (2.8) are used.

In either case, introducing (2.12) into (2.17), we get

$$\tau_w=a_1u_1\mu_w/\delta-b_1\delta(dp_1/dx)\ . \tag{2.18}$$

§ 3. Determination of $Q(\Lambda)$ and the Various Constants

In the following analysis, we shall assume (i) $(\partial T/\partial y)_w=0$, (ii) $C_p=$const., (iii) $\sigma=1$, (iv) $\mu/\mu_\infty=C(T/T_\infty)$, where

$$C=(T_w/T_\infty)^{1/2}(T_\infty+S)/(T_w+S)$$

where S is Sutherland's constant.

Then we get from (2.2) and (2.4) the well-known integral form:

$$\rho_1/\rho=T/T_1=1+[(\gamma-1)M_1{}^2/2][1-(u/u_1)^2]\ . \tag{3.1}$$

Further, if we substitute (2.7) and (2.8) in (2.2) and put $y=0$, we get

$$b(\Lambda)=-\Lambda/2\ . \tag{3.2}$$

It is well known that, if the above assumptions (i)~(iv) are satisfied, there exists a virtual incompressible flow corresponding to a real compressible flow and that such an incompressible flow can be obtained by Stewartson's transformation as follows:

$$\left.\begin{aligned} &X=\int g(x)dx\ , \\ &Y=f(x)\int_0^y \frac{\rho}{\rho_1}dy\ , \end{aligned}\right\} \tag{3.3}$$

$$U(X,\ Y)/U_1(X)=u(x,\ y)/u_1(x)\ , \tag{3.4}$$

where X, Y and U, U_1 are the coordinates and the velocity components of the transformed flow, and $g(x)$ and $f(x)$ are given known functions[13]. Assuming Pohlhausen's polynomial of degree four for the velocity distribution in the corresponding incompressible flow, we have

$$\begin{aligned} U/U_1=&(2+\Lambda_i/6)Y/\Delta-(\Lambda_i/2)(Y/\Delta)^2 \\ &-(2-\Lambda_i/2)(Y/\Delta)^3+(1-\Lambda_i/6)(Y/\Delta)^4\ , \end{aligned} \tag{3.5}$$

where

$$\Delta=f(x)\cdot\delta\int_0^1\frac{\rho}{\rho_1}d\eta\ , \tag{3.6}$$

and Λ_i is Pohlhausen's parameter of the transformed incompressible flow. If we substitut (3.1) and (2.8) in (3.3), we have

$$\begin{aligned} Y&=f(x)\int_0^y\frac{dy}{1+[(\gamma-1)M_1{}^2/2][1-(u/u_1)^2]} \\ &=\frac{f(x)\cdot\delta}{1+(\gamma-1)(M_1{}^2/2)}\int_0^\eta\frac{d\eta}{1+O(\eta^2)}\ . \end{aligned}$$

Expanding Y in power series of η and using (3.6), we have

$$Y/\Delta=[1/F(\Lambda_i)][\eta+O(\eta^3)]\ , \tag{3.7}$$

where

$$F(\Lambda_i)=\frac{T_0}{T_1}\int_0^1\frac{\rho}{\rho_1}\ d\eta\ . \tag{3.8}$$

Substituting (3.7) in (3.5), we have

$$\begin{aligned} U/U_1=&(2+\Lambda_i/6)\eta/F(\Lambda_i) \\ &-(\Lambda_i/2)[\eta/F(\Lambda_i)]^2+O(\eta^3)\ . \end{aligned} \tag{3.9}$$

From (2.8) and (3.2) we get

$$u/u_1=a(\Lambda)\eta-(\Lambda/2)\eta^2+O(\eta^3)\ . \tag{3.10}$$

Taking account of $u/u_1=U/U_1$, we get from (3.9) and (3.10)

$$a(\Lambda)=(2+\Lambda_i/6)/F(\Lambda_i)\ , \tag{3.11}$$

$$\Lambda=\Lambda_i/[F(\Lambda_i)]^2\ . \tag{3.12}$$

By substituting (3.5) and (3.8) in the relation:

$$\begin{aligned} \delta&=\int_0^\delta\frac{T}{T_1}\frac{\rho}{\rho_1}dy \\ &=\int_0^\delta\left[1+\frac{\gamma-1}{2}M_1{}^2\left\{1-\left(\frac{u}{u_1}\right)^2\right\}\right]\frac{\rho}{\rho_1}dy \\ &=\delta\int_0^1\frac{\rho}{\rho_1}\ d\eta+\frac{\gamma-1}{2}M_1{}^2\frac{\Delta}{f(x)}\int_0^1\left[1-\left(\frac{U}{U_1}\right)^2\right]d\left(\frac{Y}{\Delta}\right) \end{aligned}$$

and neglecting $O(1/M_1{}^2)$, we have

$$F(\Lambda_i)=1/[1-l(\Lambda_i)]\ , \tag{3.13}$$

where

$$\begin{aligned} l(\Lambda_i)&=\int_0^1\left(\frac{U}{U_1}\right)^2d\left(\frac{Y}{\Delta}\right) \\ &=\frac{367}{630}+\frac{71}{7560}\Lambda_i+\frac{1}{9072}\Lambda_i{}^2\ . \end{aligned} \tag{3.14}$$

By using (2.7), (3.3), (3.4), (3.5), and (3.8) and neglecting $O(1/M_1{}^2)$, we get

$$Q(\Lambda)=F(\Lambda_i)[m(\Lambda_i)-l(\Lambda_i)]\ , \tag{3.15}$$

$$\lambda(\Lambda)=O(1/M_1{}^2)\ , \tag{3.16}$$

where

$$m(\Lambda_i)=\int_0^1\left(\frac{U}{U_1}\right)d\left(\frac{Y}{\Delta}\right)=\frac{7}{10}+\frac{1}{120}\Lambda_i\ . \tag{3.17}$$

From (2.7) δ^*/δ is equal to $1-\lambda(\Lambda)$ and, if we neglect $O(1/M_1^2)$, it can be concluded from (3.16) that[†]

$$\delta^* = \delta \,. \tag{3.18}$$

Now $a(\Lambda)$, $Q(\Lambda)$, $\lambda(\Lambda)$ can be determined from (3.11)~(3.17) as functions of Λ, and $[a(\Lambda)-\{1-\lambda(\Lambda)\}\Lambda]/Q(\Lambda)$ and $a(\Lambda)$ are shown as functions of Λ in Figs. 1, 2. Thus A, B, a_1, b_1 in (2.11) and (2.12) can be determined graphically using Figs. 1, 2.

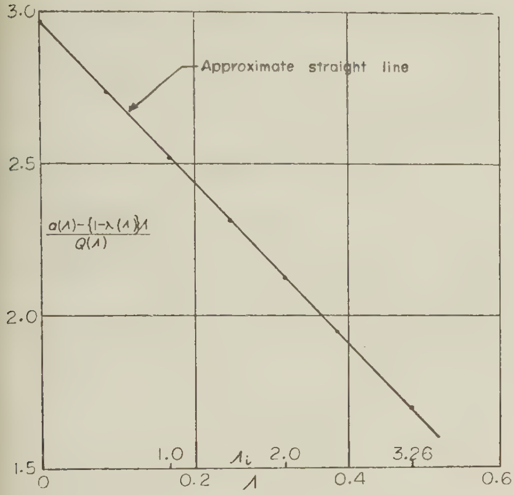

Fig. 1. The value of $[a(\Lambda)-\{1-\lambda(\Lambda)\}\Lambda]/Q(\Lambda)$.

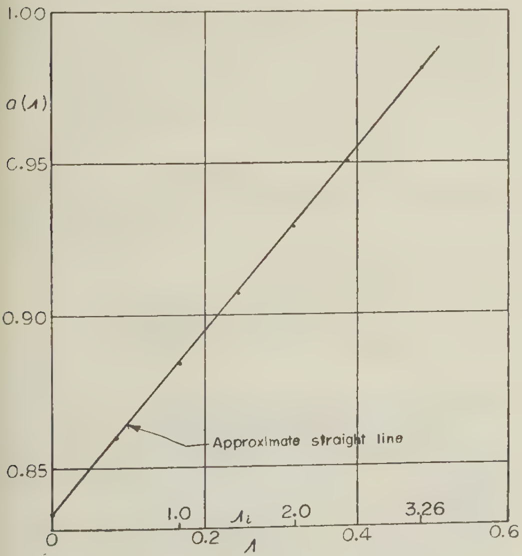

Fig. 2. The value of $a(\Lambda)$.

Stewartson[9)] has shown that, when a flat plate in the hypersonic flow has a sufficiently sharp leading edge, a similar solution exists in the neighbourhood of the leading edge (in the strong interaction region) where $p_1 \propto x^{-1/2}$ and $\Lambda_i = 3.26$. Therefore we may expect that Λ_i will change in general from 3.26 to 0 on the surface of slender bodies with a sufficiently sharp leading edge. Now as shown in Figs. 1 and 2, the curves of $[a(\Lambda)-\{1-\lambda(\Lambda)\}\Lambda]/Q(\Lambda)$ and $a(\Lambda)$ against Λ are almost straight lines in the region $0<\Lambda_i<3.26$. Thus we get the approximate relations (2.11) and (2.12), where

$$A = 2.967\,, \qquad B = -2.65\,, \tag{3.19}$$

$$a_1 = 0.835\,, \qquad b_1 = 0.302\,. \tag{3.20}$$

Further, in the above-mentioned range $Q(\Lambda)$ varies quite slightly and Q in (2.15) and (2.16) can be replaced by the mean value Q_m. ($|Q-Q_m|/Q_m < 0.02$ in this range.)

On the other hand, if $dY/dx \ll 1$ holds, where $Y(x)$ denotes the shape of the shock wave, the hypersonic small disturbance theory can be applied and u_1 can be replaced by u_∞, so that we can treat K as a constant.

§4. Formulae of the Displacement Thickness and the Local Skin-Friction Coefficient, and Comparisons with Exact Solutions

As mentioned above, Q and K in (2.15) can be treated as constants and therefore we get from (2.15)

$$\begin{aligned}\delta^{*2} &= \delta^2 \\ &= K\left(\frac{p_1}{p_\infty}\right)^{-\alpha}\left\{\int_{x_0}^{x}\left(\frac{p_1}{p_\infty}\right)^{\alpha-1}dx + \text{const.}\right\}\,,\end{aligned} \tag{4.1}$$

where the following relation has been used:

$$\begin{aligned}\mu_w &= C\mu_\infty(T_w/T_\infty) \\ &= [(\gamma-1)/2]CM_\infty^2\mu_\infty[1+O(1/M_\infty^2)]\,.\end{aligned} \tag{4.2}$$

The local skin-friction coefficient C_f can be obtained from (2.18) by using (4.2)

$$\begin{aligned}C_f = 2\tau_w/\rho_\infty u_\infty^2 &= [a_1(\gamma-1)C\mu_\infty M_\infty^2/\rho_\infty u_\infty\delta] \\ &\quad -(2b_1\delta/\rho_\infty u_\infty^2)\,dp_1/dx\,.\end{aligned} \tag{4.3}$$

In these formulae, a_1, b_1 are given by (3.20) and K, α are given in Table I.

Here, we can easily calculate (4.1) and (4.3) in the case when the pressure distribution is given by $p_1/p_\infty = p_0 x^{-1/2}$ or $p_1 = p_\infty$, in which the exact boundary layer solutions have been studied under the conditions of §3, (i)~(iv)[9),14)]. In Tables II and III the results obtained

---

[†] This fact has already been noticed by other authors, for example, Reference [9].

Table I

	α	$\alpha(\gamma=1.4)$	$\frac{\rho_\infty u_\infty K}{C\mu_\infty M_\infty^4}\equiv\tilde{K}$	$\tilde{K}(\gamma=1.4)$	Q_m
Case I	$2-2.65(\gamma-1)/\gamma$	1.243	$1.484(\gamma-1)^2$	0.2374	
Case II	$2-2.43(\gamma-1)/\gamma$	1.306	$1.455(\gamma-1)^2$	0.2328	0.2870

Table II. $(p_1/p_\infty=p_0x^{-1/2})$

	$\delta\Big/\sqrt{\frac{C\mu_\infty}{p_0\rho_\infty u_\infty}}M_\infty^2x^{3/4}$	$C_f\Big/\sqrt{\frac{Cp_0\mu_\infty}{\rho_\infty u_\infty}}x^{-3/4}$
Case I	0.520	0.754
Case II	0.524	0.750
exact solution	0.525	0.764

Table III. $(p_1=p_\infty)$

	$\delta\Big/\sqrt{\frac{C\mu_\infty}{\rho_\infty u_\infty}}M_\infty^2x^{1/2}$	$C_f\Big/\sqrt{\frac{C\mu_\infty}{\rho_\infty u_\infty}}x^{-1/2}$
Case I	0.487	0.686
Case II	0.482	0.693
exact solution	0.478	0.664

from the above theory are compared with the exact solutions.

From these tables, it may be concluded that these formulae are very useful in the almost entire region of the surface in view of the good agreement with exact solutions in both the strong interaction region $(p_1\propto x^{-1/2})$ and the weak interaction region $(p_1=p_\infty)$.

§ 5. The Viscous Flow over Slender Bodies

On the basis of the assumption that the hypersonic viscous flow over slender bodies with a sufficiently sharp leading edge is separated into the boundary layer and the inviscid layer, the pressure distributions induced by the boundary layer on a flat plate or a wedge have been studied by many authors, but these works have been mostly limited to the strong or the weak interaction region only.

Now, if we use the formula (4.1) for the boundary layer and the tangent-wedge-approximation for the inviscid layer, we can calculate the pressure distribution and the skin-friction in the entire region of the surface as follows.

In the hypersonic case when $O(1/M_1^2)$ can be neglected, $\delta^*=\delta$ and therefore the oute edge of the boundary layer coincides almos with the streamline. Then, neglecting $O(1/M_1^2$ and $O(\theta^3)$, we get

$$\theta_1=\theta_b+d\delta/dx\ , \tag*{(5.1}$$

where θ_b, θ_1 are respectively the angles o inclination of the surface element and th streamline along the outer edge of the bound-ary layer to the flight direction.

From the tangent-wedge-approximation we have, assuming that $\theta_1\ll1$,

$$\frac{p_1}{p_\infty}=1+\frac{\gamma(\gamma+1)}{4}M_\infty^2\theta_1^2$$
$$+\gamma M_\infty\theta_1\sqrt{1+\left(\frac{\gamma+1}{4}\right)^2M_\infty^2\theta_1^2}\ , \tag*{(5.2}$$

where p_1 is the pressure at the outer edge of the boundary layer. Of course, p_1 can also be regarded as the pressure on the surface of the body. From (5.1), (5.2) and (4.1), we get

$$\theta_1=\frac{1}{M_\infty}\sqrt{\frac{2}{\gamma(\gamma+1)}}\frac{(p_1/p_\infty)-1}{\sqrt{(p_1/p_\infty)+(\gamma-1)/(\gamma+1)}}\ ,$$
$$\theta_b=\theta_1-\frac{d}{dx}\left[K\left(\frac{p_1}{p_\infty}\right)^{-\alpha}\right.$$
$$\left.\times\left\{\int_{x_0}^{x}\left(\frac{p_1}{p_\infty}\right)^{\alpha-1}dx+\text{const.}\right\}\right]^{1/2}. \tag{5.3}$$

If θ_b is given, we can determine p_1, θ_1 from (5.3), and δ from (5.1), and C_f from (4.3). It is noteworthy that Eqs. (5.3) are particularly convenient for the inverse problem in which p_1 is given and θ_b is to be determined.

§ 6. The Viscous Flow over a Flat Plate

The flow over a flat plate can be calculated easily from (5.3), putting $\theta_b=0$ in (5.3). If we put

$$\left.\begin{aligned}&\sqrt{C\mu_\infty/\rho_\infty u_\infty}M_\infty^3x^{-1/2}=s\ ,\\&(\rho_\infty u_\infty/C\mu_\infty M_\infty^5)\delta=\Theta\ ,\end{aligned}\right\} \tag{6.1}$$

we have from (5.1) and (5.3)

$$\left.\begin{aligned}\Theta^2&=\left(\frac{p_1}{p_\infty}\right)^{-\alpha}\Bigg[-\beta(\gamma-1)^2\\&\qquad\times\int_{s_0}^{s}\left(\frac{p_1}{p_\infty}\right)^{\alpha-1}\frac{ds}{s^3}+\text{const.}\Bigg],\\-\frac{s^3}{2}\frac{d\Theta}{ds}&=\sqrt{\frac{2}{\gamma(\gamma+1)}}\frac{(p_1/p_\infty)-1}{\sqrt{(p_1/p_\infty)+(\gamma-1)/(\gamma+1)}}\,.\end{aligned}\right\}\tag{6.2}$$

where β is $A/2$ ($=1.484$) for Case I and $a_1/2Q_m$ ($=1.455$) for Case II. Equation (6.2) have been solved numerically for Case II† and $\gamma=1.4$. The results obtained are shown in Fig. 3, together with other author's results and Kendall's experimental values ($M_\infty=5.8$). It is clear from Fig. 3 that our results agree well witn the experimental values. When $s\gg1$ or $s\ll1$, we have the following series expansions from (6.2).

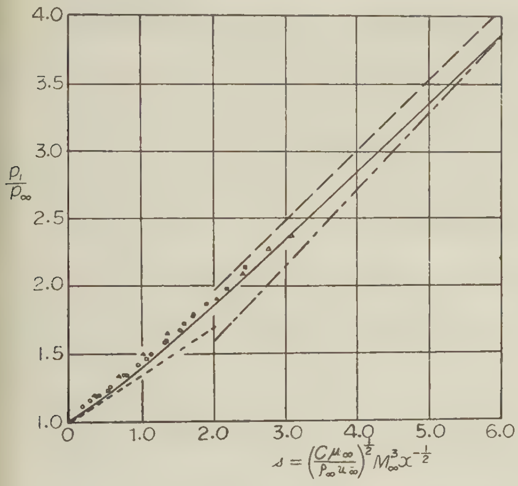

Fig. 3. The pressure distribution over the surface of a flat plate.

present theory,
------- Lees and Probstein, 1st. order weak interaction theory,
— · Lees, 1st. order strong interaction theory,
— - — - — Stewartson, 1st, order strong interaction theory,
○, □, △ Kendall, experimental values ($M_\infty=5.8$).

In the region $s\gg1$,

$$p_1/p_\infty=(3\sqrt{\beta}/4\sqrt{3-\alpha})(\gamma-1)\sqrt{\gamma(\gamma+1)}\,s+(4-\alpha)(3\gamma+1)/(9-\alpha)(\gamma+1)+\cdots\,.\tag{6.4}$$

In the region $s\ll1$,

$$p_1/p_\infty=1+(\sqrt{\beta}/2)\gamma(\gamma-1)s+(\beta/16)\gamma(\gamma+1)(\gamma-1)^2s^2+\cdots\,.\tag{5}$$

In these equations, we put the value of Case II† for α and β, and $\gamma=1.4$. The results thus obtained, as well as other authors' results for $\gamma=1.4$, are as follows.

In the region $s\gg1$, we have from (6.2)

$$p_1/p_\infty=0.510s+0.759+\cdots,$$

from Lees' results[15)]

$$p_1/p_\infty=0.52s+0.92+\cdots,$$

and from Stewartson's result[9)]

$$p_1/p_\infty=0.555s+0.489+\cdots.$$

In the region $s\ll1$, we have from (6.2)

$$p_1/p_\infty=1+0.338s+0.049s^2+\cdots.$$

and from Lees and Probstein's result[15)]

$$p_1/p_\infty=1+0.35s+0.05s^2+\cdots.$$

The agreement is very good except for Stewartson's result. The difference between the Stewartson's result and ours seems to be solely due to our use of tangent-wedge-approximation for the inviscid layer, but not due to our method of treatment of the boundary layer.

§7. Conclusion

The approximate formulae of the displacement thickness, together with those of the skin-friction, are derived by approximating the velocity profile by a polynomial of degree four of the Howarth normal distance. Comparisons with a few exact solutions are made and good agreement is obtained.

When these formulae, together with the tangent-wedge-approximation, are applied to the viscous flow over slender bodies with a sufficiently sharp leading edge, it is shown that the solution over the entire region of the surface can be calculated numerically and that the calculation is especially easily for the inverse problem. Lastly, the pressure distribution over a flat plate is calculated numerically and its result agrees well with experimental values.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol 12, No. 11, NOVEMBER, 1957

Experimental and Theoretical Investigations on the Oscillating Cylinder Viscometer for Non-Elastic Liquids

By Ali Abdel Kerim Ibrahim Ph. D. (Lond.) and
Abdel Monem I. Kabiel Ph. D. (Alexandria)
Physics Department, Faculty of Science, The University, Alexandria, Egypt

(Received June 11, 1957)

A new and exact theory of the oscillating cylinder viscometer is given for non-elastic liquids.

By introducing into the final solution a dimensionless parameter defined by:

$$\sqrt{2Ba}=x$$

where the symbols have their usual significance and x may take any value, the following expression is obtained.

$$\frac{\theta_0}{\dot{\varphi}_0}{}^2=\frac{A'n^4}{B'+C'n^2+D'n^4}$$

where A', B', C' and D' are constants and whose values depend on:—

i—The density of the liquid under study.
ii—The constants of the apparatus used.
iii—The numerical value of x chosen.

The theoretical curve representing the previous expression satisfies the experimental curve in one point (n_s, ψ_s) at which they intersect.

Hence, by substituting the value of x chosen and the value of n_s obtained in the following equation,

$$\eta=\frac{2\pi a^2}{x^2}\cdot\rho n_s$$

the value of η is determined.

Experiments have been carried out on shell motor oil X-100-60, shell motor oil X-100-50, shell motor oil X-100-40, glycerine, caster oil, pump oil, and paraffin oil.

The results obtained confirm the validity of the theory and method.

§1. Introduction

An approximate theory of the oscillating cylinder viscometer has been dealt with by Oldroyd[1], his method is to solve the differential equation in terms of Bessel function and approximated by asymptotic expansion.

Markovitz[2] devised another approximate solution. He solved the differential equation in terms of Bessel function followed by approximation using Taylor expansion.

Abdel-Kerim Ibrahim and A. M. Kabiel[3),4),5)] gave another approximate theory, very different in appearance from either that of Oldroyd or that of Markovitz, they approximate in the original equation of motion and obtain a simple and elementary solution to the problem.

This paper gives an exact theory of the oscillating cylinder viscometer i. e. free from any approximation and offers a convenient method for determining the coefficient of viscosity of non-elastic liquids.

Experimental results were obtained by us to verify the theory and method.

§ 2. The Theory

Consider a cylindrical bob of diameter 2a cms. and moment of inertia I gm. cm^2. about its major axis suspended coaxially, by a delicate torsion wire of torsion constant τ gm. cm^2. sec^{-2}, to a depth L cms. in a cup of diameter $2b$ cms. containing a liquid of density ρ gm. cm^{-3}. and viscosity coefficient η in gm. cm^{-1}. sec^{-1}.

The cup is caused to oscillate, about its vertical axis, through a very small fixed angular amplitude ϕ_0(of the order of approximately one degree) so that the liquid is following the forced oscillations of the cup.

Since the motion is axially symmetric and in two dimensions, therefore the velocity V in cm. sec^{-1}. of the liquid at any radial distance from the central vertical axis is given by:

$$\frac{1}{\nu}\frac{\partial v}{\partial t}=\frac{\partial^2 v}{\partial r^2}+\frac{1}{r}\frac{\partial v}{\partial r}-\frac{V}{r^2} \tag{1}$$

where ν is the kinematic viscosity of the liquid.

The angular displacement of the liquid at any radial distance from the central vertical axis is given by:

$$\theta=\phi\, e^{i\omega t} \tag{2}$$

where ϕ is a function of r only.
and ω is the angular velocity in sec^{-1}. of the outer cylinder.

Therefore equatian (1) may have the form:

$$\frac{\partial^2\phi}{\partial r^2}+\frac{3}{r}\frac{\partial\phi}{\partial r}+\frac{2B^2}{i}\phi=0 \tag{3}$$

where $B=(\pi\rho n/\eta)^{1/2}$
n is the frequency of the outer cylinder.

The solution of equation (3) may be obtained in terms of Bessel function of complex argument, thus,

$$\phi=(1/r)[AJ_1(i\sqrt{i}\sqrt{2}Br) \\ +\mathrm{c}y_1(i\sqrt{i}\sqrt{2}Br)] \tag{4}$$

But since $y_1(i\sqrt{i}\sqrt{2}Br)$ is infinite when Br is finite; which is an undesirable feature in the solution of practical problems, it is more convenient to take the modified Bessel function of the second kind as the second solution since it approaches zero asymptotically as Br tends to infinity and vice versa.
Hence, equation (4) can be replaced by:

$$\phi=(1/r)[A_1J_1\{-B(1-i)r\}+iC_1K_1\{B(1+i)r\}] \tag{5}$$

where A_1 and C_1 are two arbitrary constants to be determined by the boundary conditions.

Thus,

$$\theta=(1/r)[A_1J_1\{-B(1-i)r\} \\ +iC_1K_1\{B(1+i)r\}]e^{i\omega t} \tag{6}$$

and the angular velocity:

$$\dot{\theta}=\frac{iw}{r}[A_1J_1\{-B(1-i)r\}+iC_1K_1\{B(1+i)r\}]e^{i\omega t} \tag{7}$$

and the rate of change of the relative motion of adjacent layers of the liquid.

$$\frac{d\dot{\theta}}{dr}=\frac{\omega B(1+i)}{r}[C_1K_2\{B(1+i)r\} \\ +A_1J_2\{-B(1-i)r\}]e^{i\omega t} \tag{8}$$

and the angular velocity gradient in the neighbourhood of the inner cylinder.

$$\left(\frac{d\dot{\theta}}{dr}\right)_{r=a}=\frac{\omega B(1+i)}{a}[C_1K_2\{B(1+i)a\} \\ +A_1J_2\{-B(1-i)a\}]e^{i\omega t} \tag{9}$$

The Equation of Motion of the inner cylinder.

The suspended bob experiences:

i—The shearing torque C' due to the liquid, where:

$$C'=2\pi La^3\eta\left(\frac{d\dot{\theta}}{dr}\right)_{r=a} \tag{10}$$

ii—The torque C'' due to the suspension wire, where:

$$C''=-\tau\theta_0 \tag{11}$$

and θ_0 is the angular amplitude of the suspended cylinder.

As a result, the eqution of motion of the suspended cylinder is given by the following equation:

$$I(\ddot{\theta})_{r=a}=K\eta\left(\frac{d\dot{\theta}}{dr}\right)_{r=a}-\tau\theta_0 \qquad (12)$$

where $K=2\pi La^3$

Thus,

$$\theta_0=\frac{K\eta}{\tau-I\omega^2}\left(\frac{d\dot{\theta}}{dr}\right)_{r=a} \qquad (13)$$

and,

$$(\dot{\theta})_{r=a}=\frac{-K\eta}{\tau-I\omega^2}\cdot\frac{\omega^2B(1-i)}{a}e^{i\omega t}$$
$$\times[A_1J_2\{-B(1-i)a\}+C_1K_2\{B(1+i)a\}] \qquad (14)$$

where $(\dot{\theta})_{r=a}$ is the angular velocity in $\sec^{-1}$. of the liquid in the neighbourhood of the curved surface of the inner cylinder.

The boundary conditions

The arbitrary constants A_1 and C_1 are determined by the boundary conditions.

The two conditions are:

$$\left.\begin{array}{lll}\text{i—when} & r=a\,, & \theta=i\omega\theta_0 \\ \text{ii—when} & r=b\,, & \dot{\theta}=i\omega\phi_0\end{array}\right\}e^{i\omega t}$$

where ϕ_0 is the amplitude of the outer cylinder. Therefore,

$$\left.\begin{array}{l} C_1=\dfrac{\phi_0bE}{F'E-FE'} \\ \text{and} \\ A_1=\dfrac{-\phi_0bF}{F'E-FE'}\end{array}\right\} \qquad (15)$$

where:

$$E=\gamma J_1\{-B(1-i)a\}-(1+i)J_2\{-B(1-i)a\}$$
$$F=i\gamma K_1\{B(1+i)a\}-(1+i)K_2\{B(1+i)a\}$$
$$E'=J_1\{-B(1-i)b\}$$
$$F'=iK_1\{B(1+i)b\}$$

and

$$\gamma=\frac{\tau-I\omega^2}{k\eta\omega B}$$

therefore:

$$\frac{\dot{\theta}}{\phi_0}=\frac{i\omega be^{i\omega t}}{r[F'E-FE']}$$
$$\times[iEK_1\{B(1+i)r\}-FJ_1\{-B(1-i)r\}] \qquad (16)$$

and

$$\frac{d\dot{\theta}}{dr}=\frac{\omega B\phi_0b(1+i)e^{i\omega t}}{r[F'E-FE']}$$
$$\times[EK_2\{B(1+i)r\}-FJ_2\{-B(1-i)r\}] \qquad (17)$$

It is often quite convenient to consider the modulus or the absolute value, therefore on solving equation (16) we have:

$$\left|\frac{\dot{\theta}}{\phi_0}\right|^2=\frac{\omega^2b^2}{r^2}\cdot\frac{L_1^2+M_1^2}{L^2+M^2} \qquad (18)$$

Now, let:

$$\sqrt{2}\,Ba=P \qquad \sqrt{2}\,Bb=Q$$

and,

$$\sqrt{2}\,Br=S$$

Therefore:

$$L_1=-\begin{vmatrix} \mathrm{ker}_1\,S & \mathrm{kei}_1\,S & 0 & 0 \\ \gamma/2 & -\gamma/2 & 1 & 0 \\ -\mathrm{bei}_2\,P & \mathrm{ber}_2\,P & -\mathrm{bei}_1\,P & \gamma/2 \\ \mathrm{ber}_1\,P & \mathrm{ber}_1\,P & 0 & 1 \end{vmatrix} + \begin{vmatrix} \mathrm{ber}_1\,S & \mathrm{bei}_1\,S & 0 & 0 \\ \gamma/2 & -\gamma/2 & 1 & 0 \\ -\mathrm{kei}_2\,P & \mathrm{ker}_2\,P & -\mathrm{kei}_1\,P & \gamma/2 \\ \mathrm{ker}_1\,P & \mathrm{ker}_1\,P & 0 & 1 \end{vmatrix}$$

$$M_1=-\begin{vmatrix} \mathrm{ker}_1\,S & \mathrm{kei}_1\,S & 0 & 0 \\ \gamma/2 & \gamma/2 & 1 & 0 \\ \mathrm{ber}_2\,P & \mathrm{bei}_2\,P & \mathrm{bei}_1\,P & \gamma/2 \\ \mathrm{ber}_1\,P & -\mathrm{ber}_1\,P & 0 & 1 \end{vmatrix} + \begin{vmatrix} \mathrm{ber}_1\,S & \mathrm{bei}_1\,S & 0 & 0 \\ \gamma/2 & \gamma/2 & 1 & 0 \\ \mathrm{ker}_2\,P & \mathrm{kei}_2\,P & \mathrm{kei}_1\,P & \gamma/2 \\ \mathrm{ker}_1\,P & -\mathrm{ker}_1\,P & 0 & 1 \end{vmatrix}$$

$$L=-\begin{vmatrix} \mathrm{ker}_1\,Q & \mathrm{kei}_1\,Q & 0 & 0 \\ \gamma/2 & -\gamma/2 & 1 & 0 \\ -\mathrm{bei}_2\,P & \mathrm{ber}_2\,P & -\mathrm{bei}_1\,P & \gamma/2 \\ \mathrm{ber}_1\,P & \mathrm{ber}_1\,P & 0 & 1 \end{vmatrix} + \begin{vmatrix} \mathrm{ber}_1\,Q & \mathrm{bei}_1\,Q & 0 & 0 \\ \gamma/2 & -\gamma/2 & 1 & 0 \\ -\mathrm{kei}_2\,P & \mathrm{ker}_2\,P & -\mathrm{kei}_1\,P & \gamma/2 \\ \mathrm{ker}_1\,P & \mathrm{ker}_1\,P & 0 & 1 \end{vmatrix}$$

and,

$$M=-\begin{vmatrix} \mathrm{ker}_1\, Q & \mathrm{kei}_1\, Q & 0 & 0 \\ \gamma/2 & \gamma/2 & 1 & 0 \\ \mathrm{ber}_2\, \mathrm{P} & \mathrm{bei}_2\, \mathrm{P} & \mathrm{bei}_1\, \mathrm{P} & \gamma/2 \\ \mathrm{ber}_1\, \mathrm{P} & -\mathrm{ber}_1\, \mathrm{P} & 0 & 1 \end{vmatrix} + \begin{vmatrix} \mathrm{ber}_1\, Q & \mathrm{bei}_1\, Q & 0 & 0 \\ \gamma/2 & \gamma/2 & 1 & 0 \\ \mathrm{ker}_2\, \mathrm{P} & \mathrm{kei}_2 \mathrm{P} & \mathrm{kei}_1\, \mathrm{P} & \gamma/2 \\ \mathrm{ker}_1\, \mathrm{P} & -\mathrm{ker}_1\, \mathrm{P} & 0 & 1 \end{vmatrix} \tag{19}$$

Equation (18) gives the angular velocity amplitude through the liquid at any distance from the curved surface of the inner cylinder. It is related to linear velocity amplitude (V) (which is actually measured in practice) at some place; where:

$$\left|\frac{V}{\phi_0}\right| = r\left|\frac{\dot\theta}{\phi_0}\right| \tag{20}$$

also,

$$\left|\frac{\dot\theta}{\phi_0}\right|_{r=a} = \frac{\omega^2 b^2}{a^2} \cdot \frac{L_2{}^2+M_2{}^2}{L^2+M^2} \tag{21}$$

where,

$$L_2=-\begin{vmatrix} 1 & 0 & 0 \\ 1 & \mathrm{kei}_1\, \mathrm{P} & \mathrm{ker}_1\, \mathrm{P} \\ 1 & \mathrm{ber}_2\, \mathrm{P} & \mathrm{bei}_2\, \mathrm{P} \end{vmatrix} + \begin{vmatrix} 1 & 0 & 0 \\ 1 & \mathrm{bei}_1\, \mathrm{P} & \mathrm{ber}_1\, \mathrm{P} \\ 1 & \mathrm{ker}_2\, \mathrm{P} & \mathrm{bei}_2\, \mathrm{P} \end{vmatrix} \tag{22}$$

and,

$$M_2=-\begin{vmatrix} 1 & 0 & 0 \\ 1 & -\mathrm{kei}_1\, \mathrm{P} & \mathrm{ker}_1\, \mathrm{P} \\ 1 & \mathrm{bei}_2\, \mathrm{P} & \mathrm{ber}_2\, \mathrm{P} \end{vmatrix} + \begin{vmatrix} 1 & 0 & 0 \\ 1 & -\mathrm{bei}_1\, \mathrm{P} & \mathrm{ber}_1\, \mathrm{P} \\ 1 & \mathrm{kei}_2\, \mathrm{P} & \mathrm{ker}_2\, \mathrm{P} \end{vmatrix} \tag{23}$$

L and M are given by equation (19) and

$$\left|\frac{V}{\phi_0}\right|_{r=a} = a\left|\frac{\dot\theta}{\phi_0}\right|_{r=a} \tag{24}$$

Now, the rate of the relative motion of adjacent layers of the liquid can be expressed by:

$$\left|\frac{d\dot\theta}{dr}\right|^2 = \frac{w^2B^2\phi^2b^2}{r^2} \cdot \frac{L_3{}^2+M_3{}^2}{L^2+M^2} \tag{25}$$

where,

$$L_3=-\begin{vmatrix} \mathrm{ker}_2\, \mathrm{S} & \mathrm{kei}_2\, \mathrm{S} & 0 & 0 \\ -1 & 1 & 0 & 1 \\ \mathrm{bei}_2\, \mathrm{P} & \mathrm{bei}_2\, \mathrm{P} & \gamma & \mathrm{ber}_2\, \mathrm{P} \\ \mathrm{bei}_1\, \mathrm{P} & -\mathrm{ber}_1\, \mathrm{P} & 1 & 0 \end{vmatrix} + \begin{vmatrix} \mathrm{ber}_2\, \mathrm{S} & \mathrm{bei}_2\, \mathrm{S} & 0 & 0 \\ -1 & 1 & 0 & 1 \\ \mathrm{kei}_2\, \mathrm{P} & \mathrm{kei}_2\, \mathrm{P} & \gamma & \mathrm{ker}_2\, \mathrm{P} \\ \mathrm{kei}_1\, \mathrm{P} & -\mathrm{ker}_1\, \mathrm{P} & 1 & 0 \end{vmatrix}$$

and,

$$M_3=-\begin{vmatrix} \mathrm{ker}_2\, \mathrm{S} & \mathrm{kei}_2\, \mathrm{S} & 0 & 0 \\ -1 & 1 & 0 & -1 \\ \mathrm{ber}_2\, \mathrm{P} & \mathrm{ber}_2\, \mathrm{P} & \gamma & \mathrm{bei}_2\, \mathrm{P} \\ \mathrm{ber}_1\, \mathrm{P} & \mathrm{bei}_1\, \mathrm{P} & 1 & 0 \end{vmatrix} + \begin{vmatrix} \mathrm{ber}_2\, \mathrm{S} & \mathrm{bei}_2\, \mathrm{S} & 0 & 0 \\ -1 & 1 & 0 & -1 \\ \mathrm{ker}_2\, \mathrm{P} & \mathrm{ker}_2\, \mathrm{P} & \gamma & \mathrm{kei}_2\, \mathrm{P} \\ \mathrm{ker}_1\, \mathrm{P} & \mathrm{kei}_1\, \mathrm{P} & 1 & 0 \end{vmatrix} \tag{26}$$

L and M have their usual significance. and,

$$\left|\frac{d\dot{\theta}}{dr}\right|^2=\frac{\omega^2B^2\phi^2b^2}{a^2}\cdot\gamma^2\,\frac{L_2^2+M_2^2}{L^2+M^2} \tag{27}$$

Hence the velocity gradient amplitude may be obtained from the relation.

$$\left|\frac{dv}{dr}\right|=r\left|\frac{d\dot{\theta}}{dr}\right|+|\dot{\theta}| \tag{28}$$

and,

$$\left|\frac{dv}{dr}\right|_{r=a}=a\left|\frac{d\dot{\theta}}{dr}\right|_{r=a}+|\dot{\theta}|_{r=a} \tag{29}$$

Also from equations (6) and (7), it follows that,

$$|\dot{\theta}|=\omega|\theta|=\omega|\phi|\left|\frac{\theta}{\phi}\right| \tag{30}$$

Therefore, from equation (18), we have,

$$|\psi^2|=\left|\frac{\theta}{\phi_0}\right|^2=\frac{1}{\omega^2}\left|\frac{\dot{\theta}}{\phi_0}\right|^2$$

$$=\left(\frac{b}{r}\right)^2\cdot\frac{L_1^2+M_1^2}{L^2+M^2} \tag{31}$$

This gives the angular amplitude of oscillation in the liquid at any radial distance from the curved surface of the inner cylinder to that of the outer.

Also, from equation (21), we have,

$$|\psi|^2_{r=a}=\left|\frac{\theta_0}{\phi_0}\right|^2=\frac{b^2}{a^2}\cdot\frac{L_2^2+M_2^2}{L^2+M^2} \tag{32}$$

the exact relationship between the measured quantity $|\psi|_{r=a}$ and the desired quantity η.

Also equation (32) can be obtained by comparing equation (13) and (27).

Viscosity Determination

Although equation (32) represents the exact relationship between the measured quantity $|\psi|_{r=a}$ and the desired quantity η yet it is not a direct relation since the Bessel function involves η.

However, by introducing in equation (32), a dimensionless parameter defined by:

$$\sqrt{2}\,Ba=x$$

where the symbols have their usual significance and x may take any positive value, the following expression is obtained.

$$\left|\frac{\theta_0}{\phi_0}\right|^2=|\psi|^2_{r=a}=\frac{A'n^4}{B'+C'n^2+D'n^4} \tag{32}$$

where A', B', C' are constants and whose values depend on:

i—the density of the liquid.
ii—the constants of the apparatus.

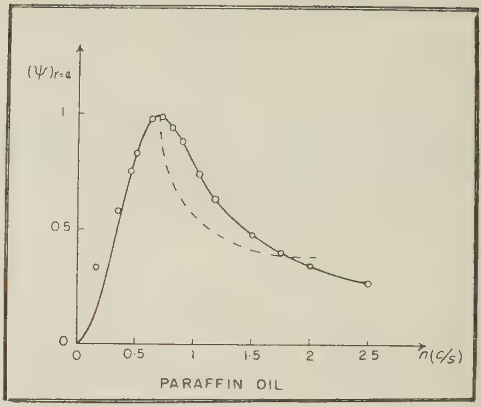

Fig. 1.

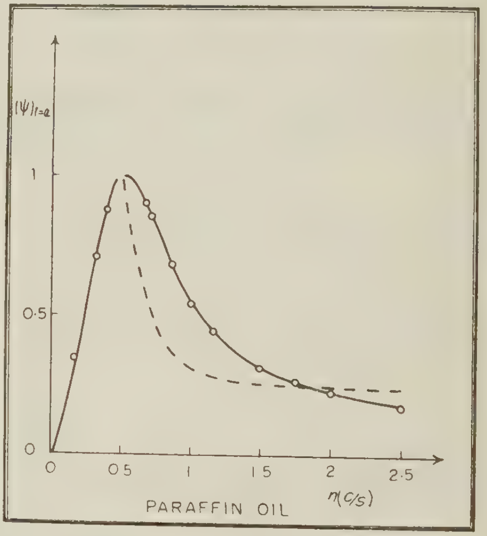

Fig. 2.

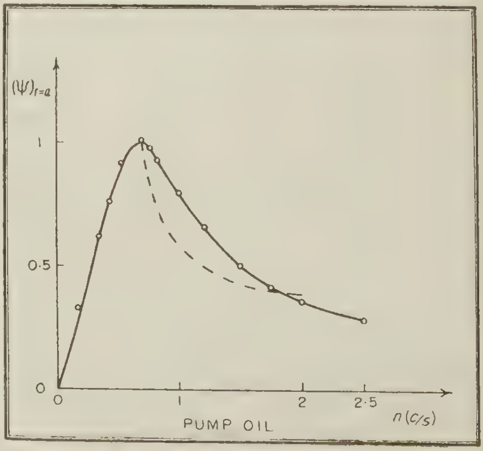

Fig. 3.

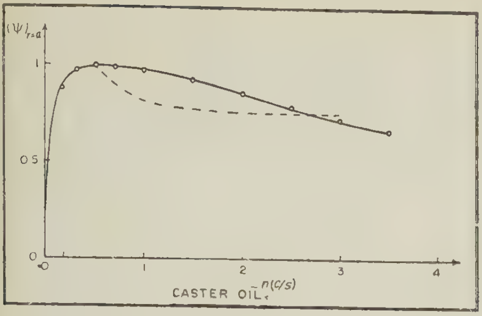

Fig. 4.

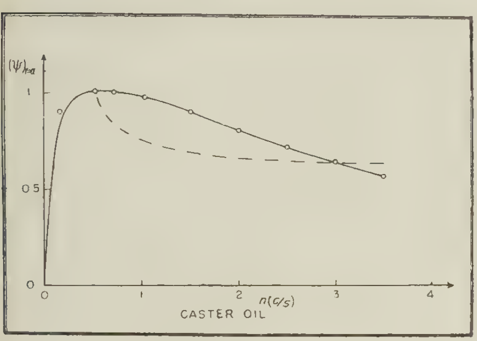

Fig. 5.

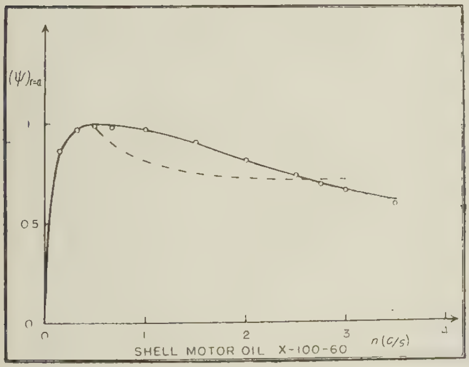

Fig. 6.

iii—the numerical value of x chosen.

The theoretical curve derived from equation (32) and the experimental curve coincide only at the point (n_s, ψ_s).

Hence, by substituting the value of x chosen and the value of n_s obtained, in the following relation:

$$\eta = \frac{2\pi \rho a^2 n_s}{x^2}$$

the value of η is determined.

In our experimental work, the values of x has been chosen:—

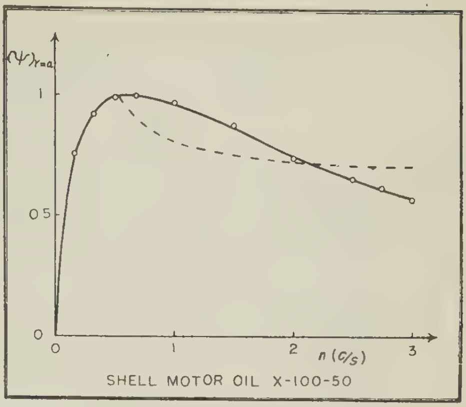

Fig. 7.

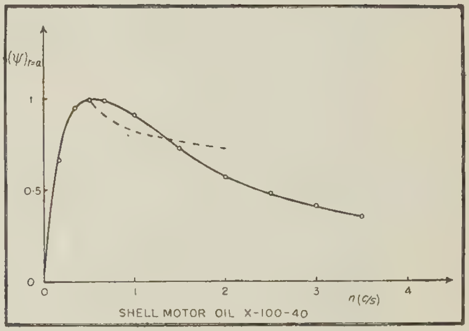

Fig. 8.

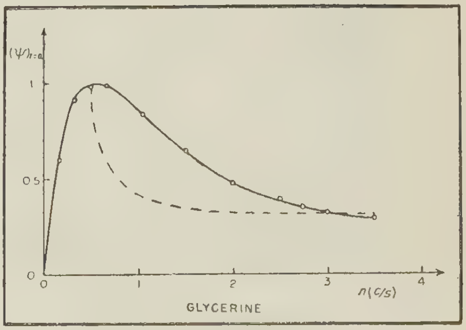

Fig. 9.

i— $\sqrt{2}\,Ba = x = 0.5$

therefore,

$$\sqrt{2}\,Bb = x\frac{b}{a} = 0.7$$

hence,

$$|\psi^2|_{r=a} = \frac{7.84}{7.846 - \frac{\gamma}{2}(0.024) + \frac{\gamma^2}{4}(0.235)}$$

where,

therefore,

$$\sqrt{2}\,Bb=1.4$$

hence,

$$|\psi|^2_{r=a}=\frac{1.96}{1.963-\frac{\gamma}{2}(0.0441)+\frac{\gamma^2}{4}(0.235)}$$

where,

$$\frac{\gamma}{2}=\frac{459.6-4\pi^2In^2}{14.35\rho Ln^2}.$$

§ 3. Results

Experiments have been carried out on paraffin oil, pump oil, caster oil, shell motor oil X-100-60 shell motor oil X-100-50, shell motor oil X-100-40 and glycerine.

Figs. (1–9) represent the variation of $(\psi)_{r=a}$ with n for the respective liquids.

The dotted line in each fig. shows the dimensionless parameter curve while the full line represents the experimental curve.

Table I provides the final results which confirm the validity of the theory and method.

§ 4. Conclusion

Considering our results in general, it appears that resonance occurs between the liquid and the inner cylinder at a certain frequency almost exactly equal to the frequency of free oscillation of the inner cylinder and the torsion wire, figs. (1–9).

Therefore copper rings were made which could be fastened on the top of the inner cylinder to change its moment of inertia and the resonant frequency of the instrument, figs. (1–2). These rings enable measurements to be made over a wide range of viscosity.

From the frequencies of the outer cylinder less than 25 c./m. and liquids of viscosity less than 5 poise nearly, the motion of the inner cylinder is not perfectly simple harmonic motion and that is probably why the observed readings in this region are subject to experimental error and inconvenient.

Also the end effect has been investigated. Since viscous forces are proportional to area,

$$F_1/F_2 = 2\pi aL/\pi a^2$$

where F_1 is the tangential viscous force at the surface of the cylinder and F_2 is the viscous force on the base or,

$$F_1/F_2 = 2L/a$$

hence, the end corrections are negligible and the effective depth of immersion is the actual length, if $a/2L$ is very small, if not the neglect of end effect will affect our results, figs. (4 and 5).

In addition, since a free surface is present at the top of the annular gap, we expect a departure from two dimensional motion, this can be made negligible by sufficiently reducing the annular gap and the amplitude of oscillation of the outer cylinder. In practice the amplitude is 1°.

Also the results are compared with that of the falling sphere method.

The results obtained in Table I confirm the validity of the theory and method discussed and indicate the sensitivity of the apparatus for slight change of temperature.

Technique of Obtaining a Minute Pinhole in a Metal Plate. II

By Tadasi Numata

Nagasaki University, Ohasi-Machi, Nagasaki

(Received July 14, 1957)

In the previous paper1) (to be refered to here as I), the author has reported a method of obtaining a minute pinhole in a metal plate having comparatively low melting point by using a needle of a glass fibre.

In order to obtain a straight minute pinhole in the metal plate whose thickness is l, it is necessary to put the needle (its length$>l$) into the molten metal against resisting force due to the surface tension of the molten metal without bending of the needle. But if l is longer than a critical length l_0, the needle can unable to be put into the molten metal without bending. One may, therefore, suppose that the maximum thickness of the metal plate having the pinhole with a diameter R is equal to the critical length l_0 corresponding to the upper limit for the stability of the undeflected equilibrium position of the needle. It is also equal to the length associated with the first mode of the bent needle when the needle originally in a vertical position is acted upon and bent by compressive forces P at the ends of the needle.

This critical length l_0 can be easily obtained by solving the Euler's equation2) for bending momen of a light needle under plausible boundary conditions. The equation is

$$\frac{d^2y}{dx^2}+k^2y=0\,, \qquad \text{(1}$$

where

$$k^2=\frac{P}{B}\,, \quad B=\frac{\pi E R^4}{64}\,,$$

B and E being the flexural rigidity and the Young's modulus, respectively. The quantity y is the deflection from the equilibrium position of the centra axis of the needle at any point whose distance from one end is x. By imposing on Eq. (1) the boundary conditions that $y=0$ when $x=0$ and $x=l$, the length of the needle corresponding to the first mode o its bending is given by $l_0k=\pi$. The corresponding load is given by $P=B\pi^2/l_0^2$. On the other hand the value of P is approximately equal to πRH, as one end of the needle is supported on the surface of the molten metal by its surface tension H. The corresponding critical length l_0 is, then, given by

$$l_0=\frac{\pi}{8}\left(\frac{ER^3}{H}\right)^{1/2}. \qquad \text{(2}$$

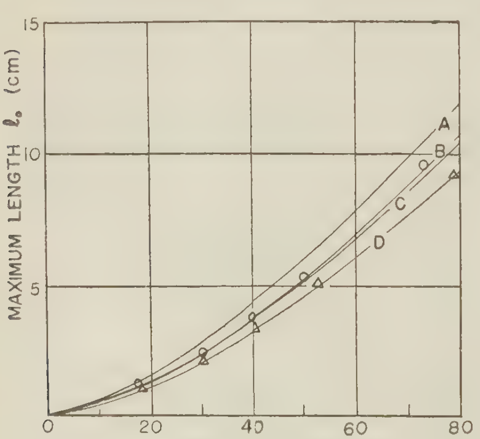

Fig. 1. Relation between the maximum length l_0 and the diameter of pinholes. Experimental: ○ (Wood's metal), △ (lead).

Fig. 1 shows the examples of the calculation by Eq. (2). The curves A and C are, respectively the calculated ones for Wood's metal and lead using fused quartz needles. The curves B and D are respectively, for Wood's metal and lead using glass needless. In the above calculations, $H=338$ dynes cm^{-1} for Wood's metal3), $H=450$ dynes cm^{-1} for lead3), $E=5\times10^{11}$ dynes cm^{-2} for glass needles, and $E=(27/R+5.9)\times10^{11}$ dynes cm^{-2} for fused quart needles5) are assumed, and the temperature dependences of H and E are not taken into account. The observed values of l_0 for Wood's metal and lead using glass needles are also shown in Fig. 1.

Finally, the author expresses his sincere thanks to Professor A. Okazaki of the Kyushu University for his encouragements.

Oscillator Strength of *M*-center of KCl

By Hiroshi OKURA

Institute of Polytechnics, Osaka City University, Osaka

(Received August 22, 1957)

Conversion of *F*-center to *M*-center and vice versa by irradiation with *F*-light and suitable heat treatment, allows us to determine the oscillator strength of *M*-center. In this report we shall describe the way and the result for KCl.

Single crystals of KCl were grown within a platinum crucible by the Kyropoulos method, using the melted reagent containing less than 0.001% divalent impurities. The crystals thus prepared were then colored additively, keeping them at 500°C for nearly eighty hours in the vapour of potassium or sodium. These colored crystals, however, naturally contain subsidiary centers other than *F*-center. In order to rule them out, the specimens were put into the furnace and kept at 500°C for one minute, after being cleaved into a thin rectangular slice as to fit the optical measurement, and then cooled down on the massive copper block at room temperature very rapidly. Care was taken that this quenching process be done in the dim light.

Every specimen subject to this treatment did show little trace of the unwanted subsidiary bands. The optical absorption measurements were carried out with a Beckman Model DU spectrophotometer at room temperature. After the absorption of such a quenched colored crystal was measured, the same specimen was exposed to the *D*-line of a sodium lamp (λ=5,890 A) for two minutes and subsequently the optical measurement was repeated, a typical results of which is shown in Fig. 1.

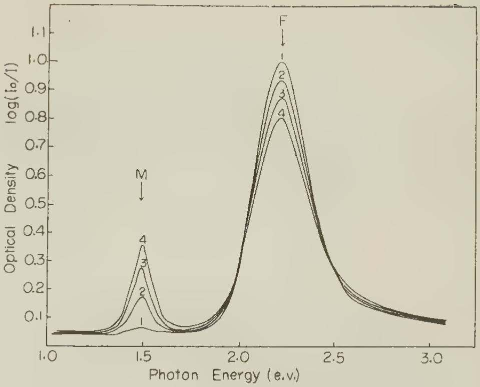

Fig. 1. Changes of the absorption curves upon successive irradiations by *F*-light (λ=5,890 A). From 1 to 4, the two-minute-exposure was repeated. The concentration of initial *F*-centers is 2.0×10^{17} 1/c.c. Measurements were done at room temperature (20°C).

Comparing the two absorption spectra with different conditions, it was confirmed that no appreciable change was observable in the region from 2,100 A to 15,000 A, except for the *F* and *M* bands. Moreover, by quenching again the irradiated specimen with the same technique described above, the original unirradiated state was quite perfectly recovered. So we safely assume that, during these short exposures, the total number of electrons is unchanged and the conversion occurs in the form of $F \rightleftarrows M$. With this assumption the increased number of electrons at *M*-center will be equal to the decreased one at *F*-centers, and this leads us to the determination of the oscillator strength for the *M*-center.

Namely, let $\Delta\alpha_F$ and $\Delta\alpha_M$ be the changes of the peak intensities of the *F* and *M* bands, respectively; then the ratio of the oscillator strengths for these two centers, using the Smakula's formula, is

Table

Specimen	Concentration of *F*-centers (c.m.$^{-3}$)	Time of Exposure (min.)	$\Delta\alpha_F$ (c.m.$^{-1}$)	$\Delta\alpha_M$ (c.m.$^{-1}$)	f_F/f_M
1*	2.0×10^{17}	2	1.22	2.24	0.58
		2	1.47	2.24	0.49
		2	1.30	1.53	0.40
2	4.8×10^{17}	2	5.30	4.70	0.30
		2	4.20	3.64	0.26
3	4.5×10^{16}	10	0.60	0.75	0.42
4	4.6×10^{16}	10	0.74	0.92	0.41

$f_F/f_M=0.41\pm0.01$.

*: Data for this specimen are shown in Fig. 1.

given by

$$\frac{f_M}{f_F}=-\frac{\Delta\alpha_M\cdot W_M}{\Delta\alpha_F\cdot W_F}$$

where W_F, W_M are the half breadths for F and M bands, their observed values being 0.36 e.v. and 0.12 e.v., respectively.

From the measured values of $\Delta\alpha$'s, we obtai f_M/f_F. These values are tabulated in the Tabl for the specimens with various *F*-center concentra tions. Taking $f_F=0.83$, we find $f_M=0.34\pm0.01$.

The author wishes to express his gratitude t Professor H. Kawamura for his helpful discussion and advices.

Anomalous Magnetic Properties of $Cu(NH_3)_4SO_4\cdot H_2O$ and $MnSO_4\cdot H_2O$

By Muneyuki DATE

Research Institute for Iron, Steel and Other Metals, Tōhoku University, Sendai

(Received October 3, 1957)

During the course of the studies on antiferromagnetism at low temperatures, we have found some anomalies in the magnetic properties of $Cu(NH_3)_4SO_4\cdot H_2O$ and of $MnSO_4\cdot H_2O$ from the measurements of paramagnetic resonance and susceptibilities. Paramagnetic resonances at 9800 and 18000 Mc/sec were observed with both substances. $Cu(NH_3)_4SO_4\cdot H_2O$ showed the anomalous broadening of the resonance lines which was reported previously by the present author[1], while $MnSO_4\cdot H_2O$ showed no resonance absorption in the liquid helium temperature region but showed a strong paramagnetic resonance above the liquid nitrogen temperatures. On the other hand, among the hydrates of $MnSO_4$, the mono-hydrate has the strongest exchange interaction, as may be seen from the narrowness of the paramagnetic resonance lines observed by Kumagai et al.[2] at room temperature. It may, then, easily be inferred that the antiferromagnetic transition may occur in the liquid helium temperature region. To clarify more precisely the magnetic anomalies of these substances, the magnetic susceptibility, specific heat measurements etc. are desired. So, we performed experiments of powder susceptibilities by the usual a.c. bridge method. The specimen of $Cu(NH_3)_4SO_4\cdot H_2O$ was obtained from the saturated ammoniac solution and that of $MnSO_4\cdot H_2O$ was obtained by heating $MnSO_4\cdot 4H_2O$ at 80°C for 5 hours. The latter specimen was carefully weighed before and after the heating and a check for the water constituent was done. More than 98% of mono-hydrate was guaranteed in our sample. The experimental results are shown in Fig. 1. χ_{curie} shows the curve that must be followed if the two salts obey the Curie law. It ma be clear that the most remarkable results are th flatness of the susceptibilities in both substance at low temperatures. One of the cause of such temperature independent susceptibility at low temperature was analyzed recently by Haseda and th present author[3] to be the non-existence of Kramer doublet for the case of Ni^{++} ion. But, as is we known, Cu^{++} and Mn^{++} have Kramers' doubl and so this cause does not apply. It may be i teresting to investigate these anomalies below 1°

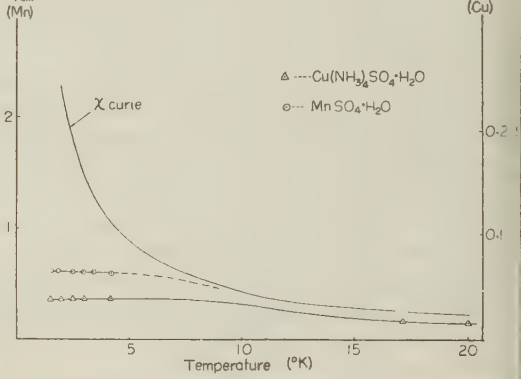

Fig. 1. Temperature dependency of magneti susceptibilities in powdered $Cu(NH_3)_4SO_4\cdot H_2$ and $Mn\ SO_4\cdot H_2O$.

The author wishes to express his cordial than to Mr. T. Haseda for the measurements of t susceptibilities and also to Prof. T. Fukuroi f encouragement given to him during the course this research. The present research was subsidize by a Research Grant form the Ministry of Educatio

Diffusion of Activator of Cathode Sleeve

By Hiroyuki Mizuno
Matsushita Electronics Corporation Takatsuki

(Received July 31, 1957)

It is pointed out by several authors that there is an affection of a diffusion coefficient of an element in an alloy from the other additional elements included in the alloy[1]. We have performed some measurements of the affection of the diffusion of magnesium activator in a cathode sleeve from the other activator elements contained in the sleeve. The test pieces were made by pressing nickel strips usually used as cathode sleeve in rolling dies till 0.005 cm thickness and shaped to a rectangular form of $0.6\times3.4\,\mathrm{cm}^2$. The rectangular filaments were cleaned completely and mounted into a vacuum equipment which was evacuated till 10^{-6} mmHg. These filaments were heated and the measurement of the magnesium left in the filament was carried out on a small group of filaments after different periods of heating life test. The results are given in Fig. 1*.

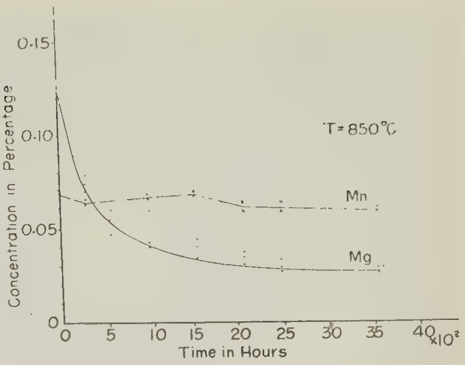

Fig. 1. The decrease of magnesium content in the sleeve with time.

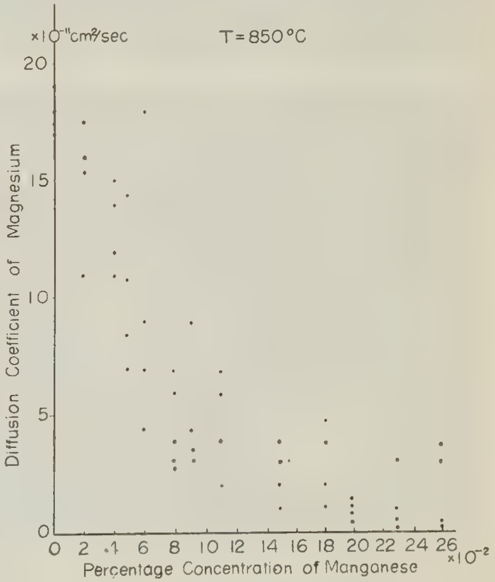

Fig. 2. The decrease of D of magnesium with increase of manganese.

Let initially the activator concentration be uniformly distributed with the constant density C_0 and it be always zero at the surface. This is a well known problem[2] with the following solution for the total amount of evolved activators Q for the time $t>0$.

$$Q=2aC_0S\left[1-\frac{8}{\pi^2}\exp\left(-D\frac{\pi^2}{4a^2}t\right)\right] \qquad (1)$$

Where D, $2a$, and S are the diffusion coefficient, filament thickness and filament surface area respectively. Then the diffusion coefficient D is given by

$$D=\frac{4a^2}{\pi^2 t}\log\frac{\pi^2}{8}\left(1+\frac{Q}{2aSC_0}\right) \qquad (2)$$

From Eq. (2), we can get the diffusion coefficient D referring to Fig. 1. In Fig. 2, we show the result of the affection of magnesium diffusion from the change of manganese contents keeping the quantity of the other elements in nickel sleeve constant as shown in Table I. From Fig. 2, we can see that the increase of manganese content may result the decrease of the diffusion coefficient of magnesium. The affections from the other elements are left for future work.

Table I. Components of Nickel.

Ni	Co	Mg	Mn	Si	Fe	S	Al	Cu
Residue	0.01	0.12	To be changed	Trace	Trace	0.001	Trace	Trace

(Weight percentage).

---

* In the Fig. 1, the decreasing curve of manganese is also given. The manganese decrease during life is negligibly small compared with magnesium, therefore the following result is given without serious error.

LCAO-MO Treatment of Phthalocyanine

By Asa CHIKAYAMA, Yuzuru OOSHIKA,
Reikiti ITOH and Isao OSHIDA.
Kobayasi Institute of Physical Research,
Kokubunji, Tokyo, Japan

(Received August 19, 1957)

The electronic energy levels of phthalocyanine are worth studying, for the dye is considered an imitation of porphyrins, which are biologically important pigments. We have calculated the electronic energy levels of metal-free phthalocyanine by simple LCAO-MO approximation, in which only the π-electrons are taken into account. As for the precise position of the two central hydrogen atoms, some ambiguity is left at present; we assume a planer structure with D_{2h} symmetry as shown in Fig. 1, according to Erdman and Corwin[1]).

There are thirty-eight centers, namely, thirty-two carbon atoms and the six nitrogen atoms without hydrogen. The number of the electrons are also thirty-eight; the lone pairs on the two nitrogen atoms linked with hydrogens are omitted from the conjugated system, because they are almost fixed on the nitrogen atoms. For the sake of simplicity, the overlap integrals are ignored, the coulombic integrals α for the carbon and the nitrogen atoms are assumed to be all equal, and the resonance integrals between adjacent atoms are regarded as β, being common to all; while the resonance integrals between non-adjacent atoms are neglected.

The secular equation that determines the energy levels, being of the thirty-eighth order, can be separated into four, the two of the tenth order and the two of the nineth order, according to the irreducible representations b_{1u}, b_{2g}, and b_{3g} and a_{1u} respectively.

The results are shown in Fig. 2, in which the value of β is taken as 23000 cm^{-1}. The transitions a_{1u}—b_{2g}, b_{2g}—b_{1u}, a_{1u}—b_{3g} and b_{3g}—b_{1u} are allowed, while others are forbidden. The calculated absorption wavelengths are compared with the experimental values of Estigneev and Kraonovskii[2]) as shown in Fig. 3. Both of them have six absorption bands in the visible region, but the spacings are so different that the identification of each band is not possible. The calculation gives two more absorption bands situated in the near infrared, which have not been found experimentally.

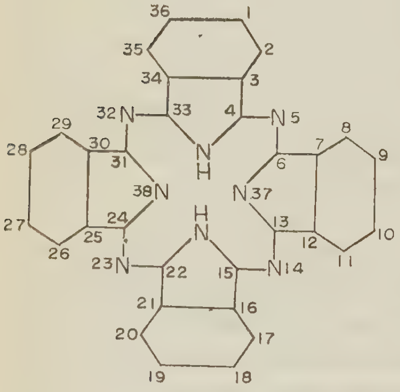

Fig. 1.

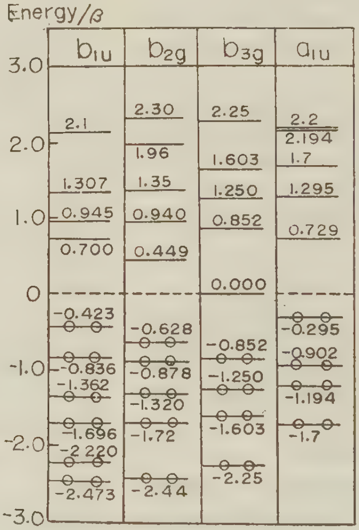

Fig. 2.

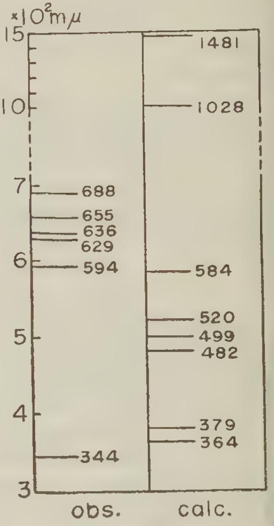

Fig. 3.

The change of the numerical value of β, and the closer approximation might give better results, but the disagreement seems to come from more basic reason, for instance, inadequate assumption concerning with the position of the hydrogen atoms at the center. The similar treatment of metal phthalocyanine is expected to throw light on this point.

The details, with similar study of porphyrins, will be published elsewhere.

Elongated Lichtenberg Figure

By Yoshimi KAMADA* and Kwai UMEDA
Department of Physics, Okayama University

(Received September 18, 1957)

With an initial aim to study the primary Lichtenberg figure in nonstationary conditions (for instance, with moving electrode or in turbulent air layer), we rotated in customary experimental arrangements the photographic plate about an axis perpendicular to the plane of itself, the needle-electrode being placed at some distance from the rotation axis, thus lightly scratching a circular track on the plate.

By this procedure the negative figure happened to be elongated along the circular track symmetrically in both directions, while the positive one didn't vary at all, as shown in Fig. 1. The lack of the expected effect of the sense of rotation may be because the formation velocity of the Lichtenberg figure is extremely high (about 10 cm/sec) in comparison with the motion of our plate, and suggests further that for the elongation it would be neither essential nor necessary to carry out the discharge in the midst of rotation. In fact, similar figures can be obtained even when the discharge takes place after stopping the rotation. Thus, the elongation seems to be caused by the metal streak rubbed on the plate glass by the sliding needle-electrode. This point of view is in favor with the fact that the amount of elongation is affected by the nature of the electrode metal and the method of rubbing the electrode on the plate (for another instance, reciprocating rubbing by hand). The distinctly different effects of the metal streak on positive and negative figures respectively may be consistent with the current theory on the Lichtenberg figure that the electron flow alone plays significant role in their formation.

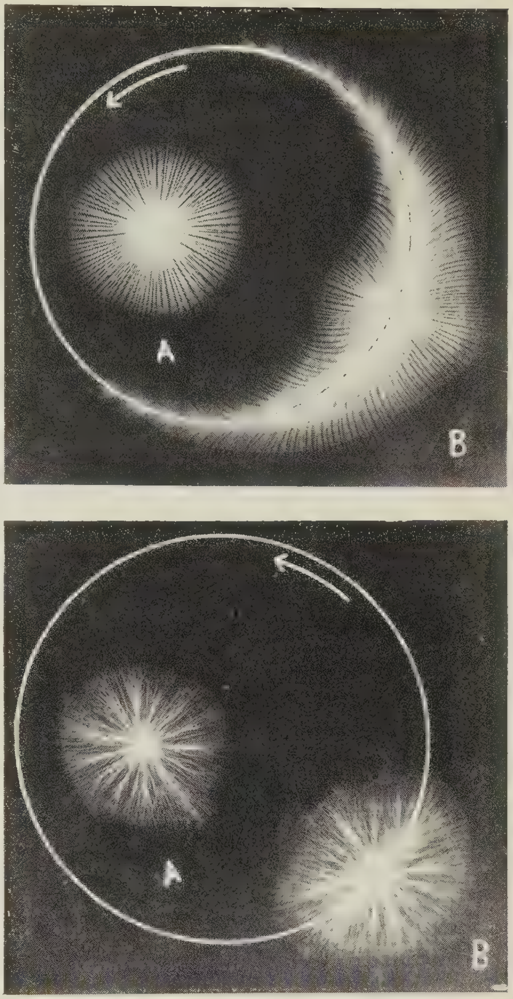

Fig. 1. Upper: negative figure; lower: positive figure. *A*: plate at rest (ordinary figure): *B*: rotating plate. Discharge voltage=about 31 kV. Rotation=about 1800 rpm. Arrow shows the sense of rotation.

Irreversible Processes and Fluctuations

By Nobuhiko SAITÔ
Department of Applied Physics
Waseda University, Tokyo

(Received September 6, 1957)

Introduction of fluctuating forces into the phenomenological equations of irreversible processes allows us to treat the irreversible processes as Brownian motions. Along this method Fokker-Planck's equation describing the probability of occurrence of a set of events is obtained and Onsager's reciprocal relations and the principle of the least dissipation of energy are derived. An interpretation of irreversible production of entropy is proposed. Finally a critique of Popov and Karanikolov's theory is given.

§1. Introduction

Since Nyquist[1)] it has been established that the irreversible process is accompanied by fluctuation and *vice versa*. Professor Takahasi[2)] of Tokyo University expressed this in the word "fluctuation is Nature's own experiment."

A method of realizing this view may be to introduce fluctuating forces in macroscopic equations of irreversible processes such as Fick's law of diffusion or Fourier's law of heat conduction.* Then the fluctuating forces should be intimately connected with the kinetic coefficients of the irreversible processes. These macroscopic equations complemented with fluctuating forces are nothing but Langevin's equations of Brownian motions. From this point of view we give a derivation of Onsager's reciprocal relation, and propose an interpretation of the irreversible production of entropy. Finally we want to criticize the theory of Popov on the derivation of reciprocal relations.

§2. Fokker-Planck Equation

As Wigner[3)] pointed out clearly, there are two ways of the demonstration of Onsager's reciprocal relations, i.e., the one is based on the assumption that the irreversible process is equivalent to the regression of fluctuation in thermal equilibrium, and the other is a natural out come from a statistical mechanical theory of irreversible processes. There are numerous theories from both points of view for the derivation of reciprocical relations. In this paper we give a derivation from the first standpoint as an application of the theory of the Brownian motion.

Consider a system with constant energy and let α_i, $i=1, 2, \cdots, N$, be a complete set of thermodynamical quantities assumed $\alpha_i=0$ in equilibrium state. The entropy is assumed to be a function of these quantities. The deviation of the entropy $\varDelta S$ from the equilibrium state is expressed in quadratic form of α_i's as follows,

$$\varDelta S=-\frac{1}{2}\sum_{i,k=1}^{N} g_{ik}\alpha_i\alpha_k \qquad (1)$$

where we have evidently

$$g_{ik}=g_{ki} \qquad (2)$$

and these coefficients form a positive definite matrix. As we confine ourselves to the linear irreversible processes, the development of $\varDelta S$ up to second order of α_i's as is expressed in (1) suffices to our consideration.

The rate of change of α_i's is assumed to obey the following phenomenological equations

$$\dot{\alpha}_i=\sum_{k=1}^{N} L_{ik}F_k \qquad (i=1, \cdots, N) \qquad (3)$$

$$F_k=\partial\varDelta S/\partial\alpha_k=-\sum_{i=1}^{N} g_{ik}\alpha_i \qquad (4)$$

where F_k's are the thermodynamical forces giving rise to the regression of the fluctuations α_q's, and L_{ik}'s are kinetic coefficients characteristic of the irreversible processes concerned. The relation to be demonstrated is the symmetric property of the kinetic coefficients, $L_{ik}=L_{ki}$. Denoting the inverse matrix of the matrix L^* by R, we have

---

* Introduction of fluctuating forces into macroscopic equations was first proposed by Hashitsume,[6)] whose theory is based on Onsager's principle of least dissipation of energy. In this paper we go backwards to lead to Onsager's principle and reciprocity of kinetic coefficients.

$$\sum_k R_{ik}L_{kj}=\delta_{ij} \tag{5}$$

$$\sum_j L_{ij}R_{jk}=\delta_{ik} \tag{6}$$

and from (3)

$$\sum_k R_{ik}\dot{\alpha}_k=F_i\ .$$

We now introduce fluctuating forces into these equations and interprete the phenomenological equations as the averaged ones of these fluctuations,

$$\sum_{k=1}^{N} R_{ik}\dot{\alpha}_k=F_i+X_i\ . \tag{6}$$

The fluctuating forces are assumed to have the following properties

i) $$\langle X_i\rangle=0 \tag{7}$$

ii) $$\langle X_i(t)X_j(t+\tau)\rangle=b_{ij}\delta(\tau) \tag*{(8)**}$$

$$b_{ij}=b_{ji} \tag{9}$$

where b is a positive definite matrix, and further

iii) the distribution $X_1, X_2, \cdots, X_N$ is N-dimensional Gaussian distribution with averages and dispersions given by (7) and (8),

$$P(X_1, X_2, \cdots, X_N)$$
$$=\frac{1}{(2\pi)^{N/2}\sqrt{\|b\|}}\exp\left\{-\frac{1}{2}\sum_{i,k}\frac{B_{ik}}{\|b\|}X_iX_k\right\} \tag{10}$$

where $\|b\|$ is the determinant of matrix b and B_{ik} is the cofactor of its *ik* element, and $B_{ik}/\|b\|$ is, therefore, *ik* element of the inverse matrix of b, which will be denoted by a_{ik}.

$$a=b^{-1}\ , \qquad a_{ik}=a_{ki}=B_{ik}/\|b\|$$

In these assumptions it is noted that the assumption (ii) implies that the correlation $\langle X_i(t)X_j(t+\tau)\rangle$ is an even function of τ, which is never realized in a system described by so-called β-variable.[4] This case will be treated in § 4.

Define

$$B_i(\Delta t, t)=\int_t^{t+\Delta t}X_i(t)dt\cong X_i(t)\Delta t$$

for small Δt, then we obtain

$$\langle B_i(\Delta t, t)B_k(\Delta t, t)\rangle=\iint_t^{t+\Delta t}\langle X_i(s_k)X(s')\rangle dsds'$$
$$=b_{ik}\Delta t\ , \tag{11}$$

which yields for the probability of a path in $\alpha\sim t$ diagram,[5]

$$\Psi\,(\text{path})\propto\exp\left\{-\frac{1}{2}\sum_{i,k}a_{ik}\int_{t_1}^{t_2}X_iX_kdt\right\}\ . \tag{12}$$

Following the method developed by Saitô and Namiki,[5] the Fokker-Planck equation for a set of Langevin equations (6) can be immediately written down by defining Lagrangian $\mathscr{L}$, momentum π_i and Hamiltonian $\mathscr{H}$ in the following way by making use of (6) and (12)

$$\mathscr{L}=\frac{1}{2}\sum_{i,k}a_{ik}X_iX_k$$
$$=\frac{1}{2}\sum_{i,k}a_{ik}(\sum_j R_{ij}\dot{\alpha}_j-F_i)(\sum_t R_{kt}\dot{\alpha}_t-F_k)\ , \tag*{(13}$$

$$\pi_i=\frac{\partial\mathscr{L}}{\partial\dot{\alpha}_i}=\frac{1}{2}\sum_{j,k}a_{jk}R_{ji}(\sum_t R_{kt}\dot{\alpha}_t-F_k)$$
$$+\frac{1}{2}\sum_{j,k}a_{jk}(\sum_t R_{jt}\dot{\alpha}_t-F_j)R_{ki}$$
$$=\sum_k(aR)_{ki}(\sum_t R_{kt}\dot{\alpha}_t-F_k) \tag*{(14}$$

and

$$\mathscr{H}=\sum\pi_i\dot{\alpha}_i-\mathscr{L}$$
$$=\frac{1}{2}\sum_{k,j}a_{kj}\{\sum_i R_{ji}\dot{\alpha}_i-F_j\}\{\sum_t R_{kt}\dot{\alpha}_t+F_k\}\ , \tag*{(15}$$

which should be rewritten as a function of and α. From (14) we have

$$\sum_i \pi_i(R^{-1}a^{-1})_{ik}=\sum_t R_{kt}\dot{\alpha}_t-F_k$$

which is substituted into (15), to obtain

$$\mathscr{H}(\pi,\alpha)=\frac{1}{2}\sum_{k,j}a_{kj}\sum_i\pi_i(R^{-1}a^{-1})_{ik}$$
$$\times\{\sum_t\pi_t(R^{-1}a^{-1})_{tj}+2F_j\}\ . \tag*{(1}$$

The Fokker-Planck equation is obtained b "quantization" $\pi_i\rightarrow-\frac{\partial}{\partial\alpha_i}$, with the result

$$\frac{\partial W}{\partial t}=\mathscr{H}\left(-\frac{\partial}{\partial\alpha}, \alpha\right)W$$
$$=-\frac{1}{2}\sum_{k,j}a_{kj}\sum_i\frac{\partial}{\partial\alpha_i}(R^{-1}a^{-1})_{ik}$$
$$\times\left\{-\sum_t\frac{\partial}{\partial\alpha_t}(R^{-1}a^{-1})_{tj}+2F_j\right\}W$$

---

* In the following we denote by A without indices the matrix whose components are defined by A_{ik}.

** Introduction of δ-function is of course a mathematical trick of the physical requirement that for small τ_0,

$$\langle X_i(t)X_j(t+\tau)\rangle=b_{ij} \qquad \tau\leq\tau_0$$
$$=0 \qquad \tau>\tau_0\ .$$

This consideration is also necessary in (33) and (34) in later section (§ 4).

$$=-\sum_i \frac{\partial}{\partial\alpha_i}\sum_j \frac{1}{2}R^{-1}_{ij}$$
$$\times\left\{-\sum_t \frac{\partial}{\partial\alpha_t}(R^{-1}a^{-1})_{tj}+2F_j\right\}W. \quad (17)$$

In this connection, it should be mentioned of the order of the factors in (16), because different order of π gives different forms of the resulting Fokker-Planck equation. This order is so chosen as to conserve the normalization of the probability[5]; i.e.,

$$\int W\prod_{i=1}^{N} d\alpha_i=1$$

and

$$\int\frac{\partial W}{\partial t}\prod_{i=1}^{N} d\alpha_i=\int\mathscr{H}W\prod_{i=1}^{N} d\alpha_i=0 .$$

§ 3. Derivation of Reciprocal Relations

The Fokker-Planck equation derived in the preceding section is not complete in respect that the constants b_{ik} or a_{ik} are merely introduced as parameters describing the fluctuations and are not connected with the kinetic coefficients. This connection is achieved by considering the equilibrium state.

In Fokker-Planck equation (17) we put

$$\frac{\partial W}{\partial t}=-\sum_i \frac{\partial}{\partial\alpha_i}(j_iW)$$

$$j_iW=\sum_j \frac{1}{2}R^{-1}_{ij}\left\{-\sum_t \frac{\partial}{\partial\alpha_t}(R^{-1}a^{-1})_{tj}+2F_j\right\}W . \quad (18)$$

This is i-th component of the current of the probability density in α-space and must vanish in equilibrium state. The conditions for vanishing j_i for $i=1, 2, \cdots, N$ require

$$\left\{-\sum_t \frac{\partial}{\partial\alpha_t}(R^{-1}a^{-1})_{tj}+2F_j\right\}W=0 . \quad (19)$$

On the other hand in equilibrium state the probability density W is given by

$$W\propto \exp(\Delta S/k)=\exp\left(-\frac{1}{2k}\sum_{i,k} g_{ik}\alpha_i\alpha_k\right). \quad (20)$$

In our treatment the existence of fluctuations is essential and in general $\alpha_i\neq 0$, though $\langle\alpha_i\rangle=0$, in equilibrium state, contrary to the statement of § 2 that $\alpha_i=0$ in equilibrium. Substitution of (20) and (4) into (19) yields

$$\left[\sum_t (R^{-1}a^{-1})_{tj}\left\{\frac{1}{k}\sum_i g_{it}\alpha_i\right\}-2\sum_i g_{ij}\alpha_i\right]W=0 . \quad (21)$$

In order for (21) to vanish identically, we have

$$\frac{1}{k}\sum_t (R^{-1}a^{-1})_{tj}g_{it}-2g_{ij}=0$$

or

$$\sum_t g_{it}(R^{-1}a^{-1})_{tj}=2kg_{ij} , \quad (22)$$

which leads immediately to

$$(R^{-1}a^{-1})_{tj}=2k\delta_{tj} \quad (23)$$

or

$$L^{-1}=R=\frac{1}{2k}a^{-1}=\frac{1}{2k}b . \quad (24)$$

Thus the correlation (8) is written as

$$\langle X_i(t)X_j(t+\tau)\rangle=2kR_{ij}\delta(\tau)$$
$$=2kL^{-1}_{ij}\delta(\tau) , \quad (25)$$

which is equivalent to the Nyquist's relation.

The symmetry property of L and R follows from the symmetry property of b as is seen in (24).

In concluding this section we rewrite Lagrangian and Fokker-Planck equation given by (13) and (18) respectively by making use of (24),

$$\mathscr{L}=\frac{1}{4k}\sum_{i,j}(\sum_t R_{it}\dot{\alpha}_t-F_i)L_{ij}(\sum_k R_{jk}\dot{\alpha}_k-F_j) \quad (26)$$

$$=\frac{1}{4k}[2\Phi(\dot{\alpha}, \dot{\alpha})+2\Psi(F, F)-2\dot{S}(\alpha)] , \quad (26')$$

where

$$\Phi(\dot{\alpha}, \dot{\alpha})=\frac{1}{2}\sum_{i,j} R_{ij}\dot{\alpha}_i\dot{\alpha}_j ,$$

$$\Psi(F, F)=\frac{1}{2}\sum_{i,j} L_{ij}F_iF_j ,$$

from which follows immediately the principle of the least dissipation of energy,[9] and

$$\frac{\partial W}{\partial t}=-\sum_i \frac{\partial}{\partial\alpha_i}j_iW$$

$$j_i=\sum_j L_{ij}\left\{-\frac{k}{W}\frac{\partial W}{\partial\alpha_j}+F_j\right\} \quad (27)$$

which is already obtained by Hashitsume.[6]

§ 4. Systems with β-variables

As is seen in relation (24), the reciprocal relation $L_{ik}=L_{ki}$ is the immediate consequence of the reciprocity of b, $b_{ik}=b_{ki}$, which, on the other hand, is equivalent to the assumption that the correlation functions of the fluctuating forces are even functions of time. This point requires further consideration. After Casimir, we divide the thermodynamical variables into two groups, α's and β's, according to the parity of time reversal, i.e., α-variables are even and β-variables are odd for time reversal. Then the development (1) of entropy ΔS must be in general separated into two groups,

$$\Delta S=-\frac{1}{2}\sum_{i,k} g_{ik}\alpha_i\alpha_k-\frac{1}{2}\sum_{\lambda,\mu} g_{\lambda\mu}\beta_\mu\beta_\lambda \qquad (28)$$

in which cross terms of α and β do not appear because the entropy is even for time reversal. Thus we have two kinds of thermodynamical forces, even and odd,

$$F_i=-\sum_k g_{ik}\alpha_k\ , \qquad (29)$$

$$F_\lambda=-\sum_\mu g_{\lambda\mu}\beta_\mu\ . \qquad (30)$$

Therefore the fluctuating forces to be introduced in phenomenological equations are even or odd, according to the parity of thermodynamical forces to be combined. That is, X_i's are even, and X_λ's are odd. Consequently, $\langle X_i(t)X_j(t+\tau)\rangle$ and $\langle X_\lambda(t)X_\mu(t+\tau)\rangle$ are even functions of τ, but $\langle X_i(t)X_\lambda(t+\tau)\rangle$ is regarded as an odd function of τ. In effect,

$$\begin{aligned}\langle X_i(t)X_\lambda(t-\tau)\rangle&=-\langle X_i(-t)X_\lambda(-t+\tau)\rangle\\&=-\langle X_i(t)X_\lambda(t+\tau)\rangle\ . \qquad (31)\end{aligned}$$

Further the relation

$$\langle X_i(t)X_\lambda(t-\tau)\rangle=\langle X_i(t+\tau)X_\lambda(t)\rangle \qquad (32)$$

leads at once to the assumption

$$\langle X_i(t)X_\lambda(t+\tau)\rangle=b_{i\lambda}\delta(\tau) \qquad (33)$$

$$\langle X_\lambda(t)X_i(t+\tau)\rangle=b_{\lambda i}\delta(\tau) \qquad (34)$$

for $\tau\geq 0$ with

$$b_{i\lambda}=-b_{\lambda i}\ . \qquad (35)$$

Then following the same procedure as in (11) and (12)*, we have

$$\langle B_i(\Delta t,t)B_\lambda(\Delta t,t)\rangle=0 \qquad (36)$$

and the probability for a path is given by

$$\Psi(\text{path})\propto\exp\left\{-\frac{1}{2}\sum_{i,k} a_{ik}\int_{t_1}^{t_2} X_iX_k dt-\frac{1}{2}\sum_{\lambda,\mu} a_{\lambda\mu}\int_{t_1}^{t_2} X_\lambda X_\mu dt\right\}\ , \qquad (37)$$

which does not contain the coefficients $a_{i\lambda}$ or $a_{\lambda i}$. However, because $a_{i\lambda}=-a_{\lambda i}$ we may write instead of (37)

$$\Psi(\text{path})\propto\exp\left\{-\frac{1}{2}\sum_{l,m} a_{lm}\int_{t_1}^{t_2} X_lX_m dt\right\} \qquad (38)$$

where l and m run for all i and λ. In what follows l,m and n stand for both i and λ. The Lagrangian $\mathscr{L}$ is

$$\begin{aligned}\mathscr{L}&=\frac{1}{2}\sum_{l,m} a_{lm}X_lX_m\\&=\frac{1}{2}\sum_{l,m} a_{lm}\Big(\sum_n R_{ln}\dot{\alpha}_n-F_l\Big)\Big(\sum_{n'} R_{mn'}\dot{\alpha}_{n'}-F_m\Big)\end{aligned} \qquad (39)$$

and defining a^* by $a^*=(a+\tilde{a})/2$, $\tilde{a}$ being the transposed matrix of a, we have for momentum π_l

$$\pi_l=\sum_m (a^*R)_{ml}\Big(\sum_{n'} R_{mn'}\dot{\alpha}_{n'}-F_m\Big) \qquad (40)$$

and for Hamiltonian $\mathscr{H}$

$$\mathscr{H}=\frac{1}{2}\sum_l \pi_l\times\sum_m\{(R^{-1}a^{*-1}aa^{*-1}\tilde{R}^{-1})_{lm}\pi_m+2(R^{-1})_{lm}F_m\}\ . \qquad (41)$$

Making use of the differential representation for momentum, we obtain for the condition of vanishing current in equilibrium

$$(R^{-1}a^{*-1}aa^{*-1}\tilde{R}^{-1})_{lm}=2k(R^{-1})_{lm} \qquad (42)$$

corresponding to (23).

Thus we have

$$a^{*-1}aa^{*-1}\tilde{R}^{-1}=2k\times\text{unit matrix}$$

or

$$\tilde{R}^{-1}=2ka^*a^{-1}a^*=2ka^*ba^*\ .$$

The matrix a^* has a form of $\left(\begin{array}{c|c} /// & 0 \\ 0 & /// \end{array}\right)$ separated into parts of α-variables and β-variables, we finally obtain

$$\left.\begin{aligned}L_{ij}&=L_{ji}=2ka_{ij}=2ka_{ji}\\L_{\lambda\mu}&=L_{\mu\lambda}=2ka_{\lambda\mu}=2ka_{\mu\lambda}\\L_{i\lambda}&=-L_{\lambda i}=2k\sum_{\mu,j} a_{\lambda\mu}{}^*b_{\mu j}a_{ji}{}^*\\&=-2k\sum_{\mu,j} a_{ij}{}^*b_{j\mu}a_{\mu\lambda}{}^*\end{aligned}\right\}\ . \qquad (44)$$

Needless to say, in the presence of magnetic field or Coriolis force, (24) and (44) still hold on inversing these external forces.

§ 5. Entropy

Consider an ensemble of N loosely coupled identical systems each of which can be treated in the above sections. The entropy of this ensemble may be defined as

---

* As is stated in the foot-note to (8), (33) and (34) mean that the correlations of the left-sides vanish for $\tau>\tau_0$, τ_0 being a small quantity. Thus in the present case the probability P of finding X_i's and X_λ's at the same time may be written as a similar form as (10), but X_iX_λ is to be regarded as $X_i(t)X_\lambda(t+\tau)$, $\tau_0>\tau>0$ and $X_\lambda X_i$ as $X_\lambda(t)X_i(t+\tau)$ with $\tau_0>\tau>0$. In this way (36) and (37) follow, with a defined as the inverse of b whose elements are b_{ij}, $b_{i\lambda}$, $b_{\mu j}$ and $b_{\lambda\mu}$.

$$S=N\int W\Delta S\prod_i d\alpha_i-kN\int W\log W\prod_i d\alpha_i\,. \tag{45}$$

The first term of (45) means the sum of the entropies of each systems, when they were isolated and were regarded as in states of thermal fluctuations, and the second is the "mixing" entropy or entropy arising form weak coupling. In equilibrium state W is equal to $W_0=e^{(-\Omega+\Delta S)/k}$, which reduces (45) to

$$S=kN\Omega-kN\int W\log(W/W_0)\prod_i d\alpha_i \tag{46}$$

S/N is considered to be an average entropy of the system. Then we have

$$\frac{dS}{dt}=N\int\frac{\partial W}{\partial t}\Delta S\prod_i d\alpha_i-kN\int\frac{\partial W}{\partial t}\log W\prod_i d\alpha_i \tag{47}$$

The first and the second terms of this equation are rewritten by making use of (27), (4) and partial integration, as follows

$$\begin{aligned}N\int&\frac{\partial W}{\partial t}\Delta S\prod_j d\alpha_j\\&=-N\int\sum_i\frac{\partial}{\partial\alpha_i}(j_iW)\Delta S\prod_j d\alpha_j\\&=N\int\sum_i j_iW\frac{\partial\Delta S}{\partial\alpha_i}\prod_j d\alpha_j\\&=N\int\sum_i j_iF_iW\prod_j d\alpha_i\end{aligned} \tag{48}$$

and

$$\begin{aligned}-kN\int&\frac{\partial W}{\partial t}\log W\prod_j d\alpha_j\\&=kN\int\sum_i\frac{\partial}{\partial\alpha_i}(j_iW)\log W\prod_j d\alpha_j\\&=-kN\int\sum_i j_i\frac{\partial W}{\partial\alpha_i}\prod_j d\alpha_j\\&=N\int[\sum_{ij}R_{ij}j_ij_j-\sum_i j_iF_i]W\prod_k d\alpha_k\end{aligned} \tag{49}$$

Thus we have

$$\frac{dS}{dt}=N\int\sum_{i,j}R_{ij}j_ij_jW\prod_k d\alpha_k \tag{50}$$

which is non negative as is to be expected. The entropy of the system increases in the average.

§6. A Critique of Popov's Theory

Recently, Popov[7] presented a theory that the phenomenological equation (3) is the first integral which has the properties $\alpha_i\to0$ at $t\to\infty$ (in equilibrium state) of the following differential equations of second order

$$\ddot{\alpha}_i=-F_i\qquad(i=1,2,\cdots,N) \tag{51}$$

and further he showed that the reciprocal relations are derived from this mathematical condition. However it seems strange to observe that equations (51) are defined only through thermodynamical quantities (4) and yet are derived from these the phenomenological equations (3) which contain kinetic coefficients of entirely different character from thermodynamical quantities. In his theory, Popov showed merely that if one write the first integrals of (51) consistent with the above condition there exist reciprocal relations between the coefficients. Popov demonstrated this in the case of two variables and Karanikolov[8] extended Popov's theory to the case of three variables.

However their calculation is easily generalized to any number of variables. Substitution of (4) into (51) gives

$$\ddot{\alpha}_i=\sum_j g_{ij}\alpha_j\qquad i=1,2,\cdots,N \tag{52}$$

which can be transformed into diagonal form

$$\ddot{x}_i=h_{ii}x_i\,,\qquad i=1,2,\cdots,N \tag{53}$$

by an orthogonal transformation T which transforms g into diagonal matrix h

$$h=TgT^{-1}\,,\qquad x=T\alpha \tag{54}$$

and then $h_{ii}>0$, because g is a positive definite matrix. Thus the solution of (53) which vanishes for $t\to\infty$ is

$$x_i=x_i(0)\exp(-\sqrt{h_{ii}}t)\,, \tag{55}$$

which yields for the first integral of (52)

$$\begin{aligned}\dot{\alpha}_i&=\sum_j T_{ij}^{-1}\dot{x}_j=-\sum_j T_{ij}^{-1}\sqrt{h_{jj}}x_j\\&=-\sum_{j,k}T_{ij}^{-1}\sqrt{h_{jj}}T_{jk}\alpha_k\\&=\sum_{j,k}T_{ij}^{-1}\sqrt{h_{jj}}T_{jk}g_{kt}^{-1}F_t\\&=\sum_{j,k}T_{ij}^{-1}\sqrt{h_{jj}}h_{jj}^{-1}T_{jk}F_k\\&=\sum_k M_{ik}F_k\end{aligned} \tag{56}$$

where the fourth line follows from the third by noting $g^{-1}=T^{-1}h^{-1}T$ and M_{ik} is defined by

$$\begin{aligned}M_{ik}&=\sum_j T_{ij}^{-1}h_{jj}^{-1/2}T_{jk}\\&=\sum_j h_{jj}^{-1/2}T_{ji}T_{jk}\end{aligned} \tag{57}$$

because T is an orthogonal transformation,

$T^{-1}_{ij}=T_{ji}$. From (57) we get immediately

$$M_{ik}=M_{ki} \tag{58}$$

which is the reciprocal relation Popov and Karanikolov want to prove. They did not show any physical meanings of the equations (51) and the coefficients M_{ik} in the first integrals. In effect the coefficients M_{ik} have nothing to do with the kinetic coefficients.

What, then, should take the place of equation (51)? Euler's equation of our system is

$$\frac{d}{dt}\frac{\partial \mathscr{L}}{\partial \dot{\alpha}_i}-\frac{\partial \mathscr{L}}{\partial \alpha_i}=0 \tag{59}$$

where Lagragian $\mathscr{L}$ is given by (26). This equation is written, making use of the reciprocal relation of L_{ik}, as

$$\sum_j R_{ij}\ddot{\alpha}_j+\sum_j (gL)_{ij}F_j=0$$

or

$$\begin{aligned}\ddot{\alpha}_i&=-\sum_j (LgL)_{ij}F_j\\&=\sum_j(LgLg)_{ij}\alpha_j\end{aligned} \tag{60}$$

This should be used instead of (51). Following the same procedure as from (51) to (56), we define a diagonal matrix S by means of an orthogonal transformation T,

$$S=T(Lg)T^{-1}, \qquad g=L^{-1}T^{-1}ST, \tag{61}$$

then we have

$$\dot{\alpha}_i=\sum_j K_{ij}F_j \tag{62}$$

and

$$\begin{aligned}K_{ij}&=\sum T^{-1}_{ik}S_{kk}T_{kt}g^{-1}_{tj}\\&=\sum T^{-1}_{ik}S_{kk}T_{kt}(T^{-1}S^{-1}TL)_{tj}\\&=L_{ij}\end{aligned} \tag{63}$$

The above consideration is nothing but a conclusion of the Onsager and Machlup's variational principle.[9]

Note added on Oct. 12.

After submitting this manuscript to the Physical Society of Japan a paper of Tisza and Mannig (Phys. Rev. **105** (1957) 1695) came to the author's attention, which is closely related to this paper. Their theory is based on the property of the Lagrangian of Onsager-Machlup's theory (which they call OM function) as is done by Hashitsume, and is developed for one variable. Nothing is said about reciprocity relation, but mention is made of the spectral representation.

The Measurements of the Galvanomagnetic Tensors of Bismuth

By Toshihiro OKADA

Department of Physics, Faculty of Science, Kyushu University

(Received October 19, 1956)

The anisotoropy of the galvanomagnetic effects in the single crystals of pure bismuth was investigated at the temperatures between −160° and 45°C. The results were analysed by the phenomenological theory of the galvanomagnetic effects. Two components of the resistivity tensor, two components of the Hall tensor, eight components of the magnetoresistance tensor and six components of the third order galvanomagnetic tensor were determined as the functions of temperature.

§ 1. Introduction

The galvanomagnetic effects of bismuth are very remarkable even in weak magnetic field, and the anisotrioy of these effects of single crystals have been studied extensively.[1)-8)] When we intend to carry out the complete measurements, it seems to be necessary to consider these effects phenomenologically by means of tensor analysis from the view-points of Onsager's reciprocal relation and rotatory symmetry of crystals.[9)-12)] The results obtained by these considerations were employed for the design of the experimental apparatus and for the preparation of specimens. In this work, the eighteen components of the galvanomagnetic tensors were determined as the functions of the temperature between −160°∼45°C, and the preliminary report has been published already.[13)] Recently Abeles and Meiboom[14)] performed the similar measurements and determined some components of the galvanomagnetic tensors. Their values are nearly concordant with this work in general cases, but in some components the discrepancy of about factor 2 were found between two measurements.

§ 2. Tensor Consideration

According to the phenomenological theory the galvanomagnetic effects of a single crystal can be expressed by the following tensor-equation[11),12)] if the electric field is not too strong:

$$E_i=\rho_{ij}(\boldsymbol{H})I_j+\varepsilon_{ijk}I_jR_k(\boldsymbol{H})\,, \qquad (1)$$

where

$$\rho_{ij}(\boldsymbol{H})=\rho_{ji}(\boldsymbol{H})\,.$$

In Eq. (1), $E_i(i=1,2,3)$ is the component of the electric field which is applied to the crystal, $I_j(j=1,2,3)$ the component of the current density flowing through the crystal, $\rho_{ij}(\boldsymbol{H})$ is the even function with respect to $\boldsymbol{H}$, and $R_k(\boldsymbol{H})$ is the odd function. ε_{ijk} is Eddington's tensor of the third rank.*

When the magnetic field is weak, we can expand $\rho_{ij}(\boldsymbol{H})$ and $R_k(\boldsymbol{H})$ in the power series near zero field as follows:

$$\left.\begin{aligned}\rho_{ij}(\boldsymbol{H})&=\rho_{ij}+\rho_{ij,mn}H_mH_n+\cdots\,,\\ R_k(\boldsymbol{H})&=R_{k,m}H_m+R_{k,mno}H_mH_nH_o+\cdots\end{aligned}\right\}\qquad(2)$$

ρ_{ij} is the resistivity tensor of the second rank, whose subscripts can be interchangeable; $\rho_{ij,mn}$ is the magnetoresistance tensor of the fourth rank, which has the interchangeability with respects to pairs of subscripts before or after the comma; $R_{k,m}$ is the Hall tensor of the second rank; $R_{k,mno}$ is the third order galvanomagnetic tensor of the fourth rank, whose subscripts *mno* can be interchanged with each other[12)].

A bismuth crystal has the ratotory symmetry D_{3d} which is galvanomagnetically equivalent to D_3 having one trigonal axis and three binary axes. If we assume the trigonal axis as the third axis of the cartesian coordinate (x_3), and one of binary axes as the first (x_1), and the axis which is perpendicular to both x_1 and x_3 as the second (x_2), the components of the galvanomagnetic tensors can be expressed as follows[12)]:

$$\rho_{ij}=\begin{pmatrix}\rho_{11} & 0 & 0\\ 0 & \rho_{11} & 0\\ 0 & 0 & \rho_{33}\end{pmatrix}, \qquad (3)$$

---

* ε_{ijk} is zero if $i=j$ or k, or $k=j$, but equal to $+1$ if $ijk=123$, 231 or 312, and equal to -1 if $ijk=213$, 321 or 132.

$$\rho_{ij,mn}=\begin{pmatrix} \rho_{11,11} & \rho_{11,22} & \rho_{11,33} & \rho_{11,23} & 0 & 0 \\ \rho_{11,22} & \rho_{11,11} & \rho_{11,33} & -\rho_{11,23} & 0 & 0 \\ \rho_{33,11} & \rho_{33,11} & \rho_{33,33} & 0 & 0 & 0 \\ \rho_{23,11} & -\rho_{23,11} & 0 & \rho_{23,23} & 0 & 0 \\ 0 & 0 & 0 & 0 & \rho_{23,23} & \rho_{23,11} \\ 0 & 0 & 0 & 0 & \rho_{11,23} & \frac{1}{2}(\rho_{11,11}-\rho_{11,22}) \end{pmatrix}, \qquad (4$$

$$R_{k,m}=\begin{pmatrix} R_{1,1} & 0 & 0 \\ 0 & R_{1,1} & 0 \\ 0 & 0 & R_{3,3} \end{pmatrix}, \qquad (5$$

$$R_{k,mno}=\begin{pmatrix} R_{1,111} & 0 & \frac{1}{3}R_{1,111} & 0 & 0 & R_{1,123} & 0 & R_{1,133} & 0 & 0 \\ 0 & \frac{1}{3}R_{1,111} & 0 & R_{1,111} & R_{1,123} & 0 & -R_{1,123} & 0 & R_{1,133} & 0 \\ 0 & R_{3,112} & 0 & -R_{3,112} & R_{3,113} & 0 & R_{3,113} & 0 & 0 & R_{3,333} \end{pmatrix}. \qquad (6$$

In the two dimensional representation of the last tensor, the subscript k is arrayed vertically, and the subscripts mno are arrayed horizontally in such a sequence as 111, 112=121=211, 122=212=221, 222, 113=131=311, 123=132=213=231=312=321, 223=232=322, 133=313=331, 233=323=332 and 333.

It can easily seen that there are two independent material constants for ρ_{ij}, eight for $\rho_{ij,mn}$, two for $R_{k,m}$ and six for $R_{k,mno}$, respectively. In order to measure all of the above shown components, it seems to be necessary to perform three sets of measurements about several types of specimens got from one single crystal. The shape of the specimen should be a rectangular parallelepipedon elongated in such a direction that makes the angle θ_2 with the trigonal axis in the x_1-x_3 plane (see Fig. 1(a) and (b)); its cross section should be square or nearly square, and the elongated side faces should be parallel or perpendicular to x_2-axis.

The first set of measurements As shown in Fig. 1(a), under the external magnetic field $\boldsymbol{H}$ in such a direction which makes the angle φ from x_3-axis in x_1-x_3 plane, the electric field E_1' along the long side of the specimen and the Hall field E_2 along x_2-axis should be measured by two pairs of probes when the current I_1' passes through the specimen. The resistivity E_1'/I_1' may b calculated by the following method. As th direction cosine of the current vector $\boldsymbol{I}_1'$, i $(\sin\theta_2,\ 0,\ \cos\theta_2)$, we have

$$\boldsymbol{I}_1'=(I_1'\sin\theta_2,\ 0,\ I_1'\cos\theta_2)\ , \qquad (7$$

then Eq. (1) reduces to

$$\frac{E_1}{I_1'}=\sin\theta_2\rho_{11}(\boldsymbol{H})+\cos\theta_2\rho_{13}(\boldsymbol{H})-\cos\theta_2 R_2(\boldsymbol{H})\ ,$$

$$\frac{E_2}{I_1'}=\sin\theta_2\rho_{12}(\boldsymbol{H})+\cos\theta_2\rho_{23}(\boldsymbol{H})+\cos\theta_2 R_1(\boldsymbol{H})-\sin\theta_2 R_3(\boldsymbol{H})\ ,$$

$$\frac{E_3}{I_1'}=\sin\theta_2\rho_{13}(\boldsymbol{H})+\cos\theta_2\rho_{33}(\boldsymbol{H})+\sin\theta_2 R_2(\boldsymbol{H})\ , \qquad (8$$

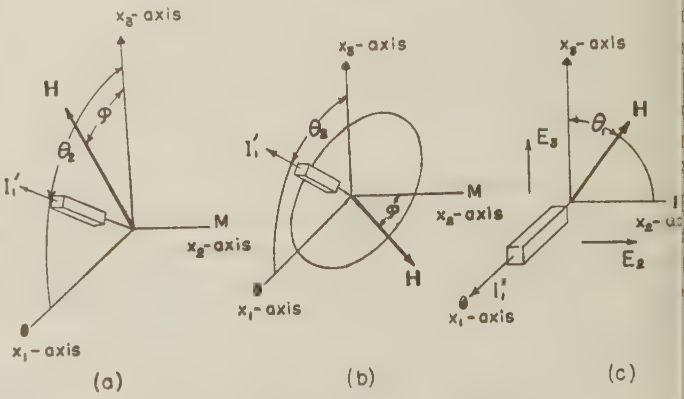

Fig. 1. Geometry of measurements.
(a) For the first set. (b) For the second set.
(c) For the third set.

so the resistivity is given by

$$\frac{E_1'}{I_1'}=(\sin\theta_2 E_1+\cos\theta_2 E_3)/I_1'$$
$$=\sin^2\theta_2\rho_{11}(\boldsymbol{H})+\cos^2\theta_2\rho_{33}(\boldsymbol{H})+2\sin\theta_2\cos\theta_2\rho_{13}(\boldsymbol{H})\,, \tag{9}$$

in which the terms concerning the Hall effect vanish. Expanding as the power series of H_i as shown by Eq. (2), we have

$$\left.\begin{aligned}\rho_{11}(\boldsymbol{H})&=\rho_{11}+\rho_{11,11}H_1^2+\rho_{11,33}H_3^2+\cdots,\\ \rho_{33}(\boldsymbol{H})&=\rho_{33}+\rho_{33,11}H_1^2+\rho_{33,33}H_3^2+\cdots,\\ \rho_{13}(\boldsymbol{H})&=2\rho_{23,23}H_2H_3+\cdots\,.\end{aligned}\right\} \tag{10}$$

From $\boldsymbol{H}=(H\sin\varphi,\ 0,\ H\cos\varphi)$, Eq. (9) reduces to

$$\frac{E_1'}{I_1'}=\rho^{(2)}(\theta_2)+H^2\rho^{(4)}(\theta_2,\varphi)+\cdots, \tag{11}$$

where

$$\rho^{(2)}(\theta_2)=\rho_{11}\sin^2\theta_2+\rho_{33}\cos^2\theta_2\,, \tag{12}$$

$$\begin{aligned}\rho^{(4)}(\theta_2)=&\left\{\frac{\rho_{11,11}+\rho_{11,33}}{2}\sin^2\theta_2+\frac{\rho_{33,11}+\rho_{33,33}}{2}\cos^2\theta_2\right\}\\ &+\left\{\frac{\rho_{11,33}-\rho_{11,11}}{2}\sin^2\theta_2+\frac{\rho_{33,33}-\rho_{33,11}}{2}\cos^2\theta_2\right\}\cos 2\varphi\\ &+\{\rho_{23,23}\sin 2\theta_2\}\sin 2\varphi\,.\end{aligned} \tag{13}$$

By measuring the resistance under the magnetic field, we can determine the value of $\rho^{(2)}(\theta_2)$ as a function of θ_2 and the value of $\rho^{(4)}(\theta_2,\varphi)$ as a function of θ_2 and φ. Eq. (12) shows that $\rho^{(2)}(\theta_2)$ has the period π for θ_2, while Eq. (13) shows that $\rho^{(4)}(\theta_2,\varphi)$ consists of three terms; the first one is independent of φ, and the second and third are proportional to $\cos 2\varphi$ and $\sin 2\varphi$, respectively. From analysis of the experimental results concerning $\rho^{(4)}(\theta_2,\varphi)$, the θ_2-dependency of the factors within the large brackets can be found so as to determine the numerical values of $\rho_{11,11}$, $\rho_{11,33}$, $\rho_{33,11}$, $\rho_{33,33}$ and $\rho_{23,23}$, although the values of the remaining components $\rho_{11,22}$, $\rho_{23,11}$ and $\rho_{11,23}$ cannot be obtained by these measurements. The components of the Hall tensor $R_{k,m}$ may be found from Eq. (8); as the direction cosines of $\boldsymbol{I}_1'$ are $(\sin\theta_2,\ 0,\ \cos\theta_2)$, and those of E_2 $(0, 1, 0)$, the components of the unit vector which is perpendicular to both $\boldsymbol{I}_1'$ and E_2 are $(-\cos\theta_2,\ 0,\ \sin\theta_2)$. Then the odd part[*] of E_2/I_1' becomes $\cos\theta_2 R_1(\boldsymbol{H})-\sin\theta R_3(\boldsymbol{H})$, so we have

$$\begin{aligned}\text{Odd Part of } E_2/I_1'&=R^{(2)}(\theta_2,\varphi)H\\ &=(R_{1,1}\cos\theta_2\sin\varphi-R_{3,3}\sin\theta_2\cos\varphi)H\,,\end{aligned} \tag{14}$$

if the first terms in the power expansion of $R_k(\boldsymbol{H})$ is retained. $R^{(2)}(\theta_2,\varphi)$ has the period 2π with respect to φ, and its amplitude is given by

$$\{(R_{1,1}\cos\theta_2)^2+(R_{3,3}\sin\theta_2)^2\}^{1/2}\,. \tag{15}$$

The second set of measurements The specimens used in these measurements are the same as in the first set; but the magnetic field is applied always in a direction perpendicular to the current $\boldsymbol{I}_1'$ as is shown in Fig. 1(b). As the direction cosines of $\boldsymbol{H}$ are $(\sin\varphi\cos\theta_2,\ \cos\varphi,\ -\sin\varphi\sin\theta_2)$, where φ is measured from x_2-axis clockwise in the plane perpendicular to $\boldsymbol{I}_1'$, the resistivity is calculated by the following equations:

$$\frac{E_1'}{I_1'}=\rho_{11}+H^2\left[\left(\frac{\rho_{11,22}+\rho_{11,33}}{2}\right)+\left(\frac{\rho_{11,22}-\rho_{11,33}}{2}\right)\cos 2\varphi-\rho_{11,23}\sin 2\varphi\right], \qquad (\theta_2=90^\circ)$$

---

[*] The term which is odd with respect to $\boldsymbol{H}$ in the second equation of (8) could be obtained by measuring $\frac{1}{2}\left\{\frac{E_2(\boldsymbol{H})}{I_1'}-\frac{E_2(-\boldsymbol{H})}{I_1'}\right\}$, that is, one half of the difference between E_2/I_1' for a magnetic field $(\boldsymbol{H})$ and that for the reverse one $(-\boldsymbol{H})$.

$$=\frac{\rho_{11}+\rho_{33}}{2}+H^2\Bigg[\left(\frac{\rho_{11,11}+\rho_{11,33}+\rho_{33,11}+\rho_{33,33}}{2}-\rho_{23,23}\right)\sin^2\varphi$$

$$+\frac{\rho_{11,22}+\rho_{33,11}}{2}\cos^2\varphi+\left(\frac{\rho_{23,11}}{\sqrt{2}}-\frac{\rho_{11,23}}{2}\right)\sin 2\varphi\Bigg]\,, \qquad (\theta_2=45^\circ)$$

$$=\rho_{33}+H^2[\rho_{33,11}]\,. \qquad (\theta_2=0^\circ) \qquad (1$$

And from the second equation of (8) we have

$$\text{Odd Part of } E_2/I_1'=(R_{1,1}\cos^2\theta_2+R_{3,3}\sin^2\theta_2)\sin\varphi H\,, \qquad (1$$

which may be used for the determination of $R_{1,1}$ and $R_{3,3}$ in some cases, and

$$\text{Even Part of } E_2/I_1'=-\rho_{23,11}H^2\,, \qquad (\text{if } \theta_2=0) \qquad (1$$

which corresponds to the planar Hall effect. By means of Eqs. (16) and (18) we can find th values of $\rho_{11,22}$, $\rho_{23,11}$, $\rho_{11,33}$ and $\rho_{11,23}$.

The third set of measurements The six components of $R_{k,mno}$ can be determined by th following method. For the specimen with $\theta_2=0$, two pair of probes, which are set perp dicular with each other, are used to measure the electric fields along x_2- and x_3-axes. If th magnetic field is applied in the x_2-x_3 plane as shown in Fig. 1(c), $R_k(\boldsymbol{H})$ may be expande as follows:

$$\left.\begin{aligned}
&R_1(\boldsymbol{H})=0\,,\\
&R_2(\boldsymbol{H})=R_{1,1}H_2+R_{1,111}H_2^3-3R_{1,123}H_2^2H_3+3R_{1,133}H_2H_3^2\,,\\
&R_3(\boldsymbol{H})=R_{3,3}H_3-R_{3,112}H_2^3+3R_{3,113}H_2^2H_3+R_{3,333}H_3^3\,.
\end{aligned}\right\} \qquad (1$$

Let θ_1 be the angle between the magnetic field and x_3-axis, then we have

$$\text{Odd Part of } E_2/I_1'=-R_{3,3}\cos\theta_1 H+R_2^{(4)}(\theta_1)H^3\,, \qquad (2$$

where

$$R_2^{(4)}(\theta_1)=R_{3,112}\sin^3\theta_1-3R_{3,113}\sin^2\theta_1\cos\theta_1-R_{3,333}\cos^3\theta_1\,, \qquad (2$$

$$\text{Odd Part of } E_3/I_1'=R_{1,1}\sin\theta_1 H+R_3^{(4)}(\theta_1)H^3\,, \qquad (2$$

where

$$R_3^{(4)}(\theta_1)=R_{1,111}\sin^3\theta_1-3R_{1,123}\sin^2\theta_1\cos\theta_1+3R_{1,133}\sin\theta_1\cos^2\theta_1\,. \qquad (2$$

From the θ_1-dependencies of $R_2^{(4)}(\theta_1)$ and $R_3^{(4)}(\theta_1)$, six components of $R_{k,mno}$ can be calculate

By means of these sets of measurements described in this section, we can find values all the components of the galvanomagnetic tensors ρ_{ij}, $\rho_{ij,mn}$, $R_{k,m}$ and $R_{k,mno}$.

§ 3. Experimental

An ingot of bismuth, whose length is about 80 mm and diameter is about 8 mm, was made of Merck "extra pure" bismuth. The ingot was zone-refined five times with the zone-width of 10∼15 mm and with the speed of 15 mm/hr, then this became a single crystal. Specimens were cut off from its middle part. The purity was not determined by the quantitative analysis, but supposed to be the order of four-nine.*

As is well known, the cleavage planes of bismuth crystal are (000,1), and on the planes are seen many faint stripes intersectin by the angle 120° with each other. Th direction of the stripes proved to be coincide with binary axes by X-ray photograph. R ferring to the cleavage planes and bina stripes six specimens with the following sha were prepared: the length is 6∼8 mm, t cross section is nearly square (2×2 mm²). S different values are taken for θ_2, namely 0 30°, 45°, 60°, 75° and 90°. The shaping a grinding of specimens are made by means a watch-lathe equipped with the tip of denta grinder.** The dimension of specimens w measured within the accuracy of 0.01 mm by a screw-micrometer or by a comparator. The error of the angle θ_2 may be $\pm(1\sim2)°$.

---

* By spectroscopic qualitative analysis the existence of the following elements was proved: Ag, As, Cu, Fe, Hg, In, Ni, Pb and Sn (in alphabetical arrangement). The author is indebted to Mr. H. Suzuki for this analysis.

** For the preparation of specimen the author indebted to Messrs. K. Hirakawa and A. Okazaki

The resistance and the Hall voltage were measured by means of a D. C. potentiometer and a galvanometer. The magnetic field of 200~1500 gauss was supplied from an electro-magnet, which can be rotated around the vertical axis to vary φ or θ_1. The intensity of the magnetic field was measured by a fluxmeter and a search-coil calibrated by nuclear resonance.

We must take care that large magnetic field should not be applied to specimens, because the galvanomagnetic tensors $\rho_{ij,mn}$ and $R_{k,mno}$ are the coefficients of the power expansions of $\rho_{ij}(\boldsymbol{H})$ and $R_k(\boldsymbol{H})$, respectively, near the zero point of the field.

§4. Results

By the method described in §2, the components of the galvanomagnetic tensors ρ_{ij}, $\rho_{ij,mn}$, and $R_{k,m}$ were obtained for the following four standard temperatures, namely 45°, 0°, −70° and −160°C; but as for $R_{k,mno}$ the measurements were carried out only for the three temperatures 27.₅°, −70° and −167°C.

a) The components ρ_{ij} The resistivity was measured as the function of temperature for the specimens whose θ_2 are 0°, 30°, 45°, 60° and 90°. Results for 0°C and 45°C are shown in Fig. 2; in which $\sin^2\theta_2$ is taken as the abscissa and $\rho^{(2)}(\theta_2)$ as the ordinate. According to Eq. (12), $\rho^{(2)}(\theta_2)$ should be a linear function of $\sin^2\theta_2$. In Fig. 2 the observed values are represented by crosses, which seem to be on straight lines. The probable values of ρ_{11} and ρ_{33} can be easily obtained from such lines, and their temperature-dependency is shown in Fig. 3, and their numerical values are tabulated in Table I with their estimated errors.

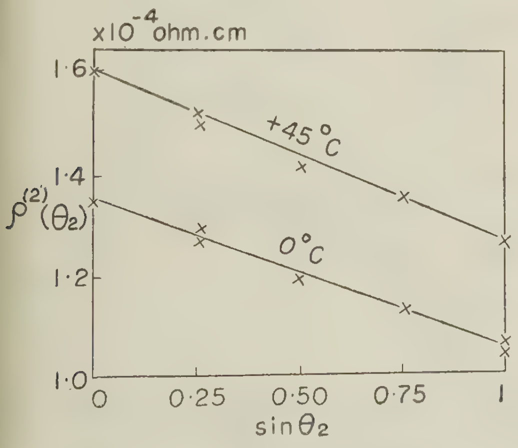

Fig. 2. θ_2-dependencies of $\rho^{(2)}$.

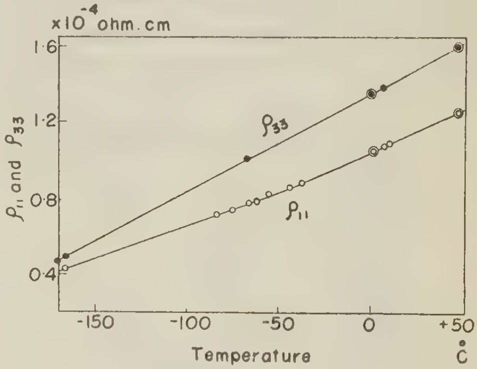

Fig. 3. Temperature dependencies of ρ_{11} and ρ_{33}. The values shown by ⊙ and ◎ are obtained from the lines drawn in Fig. 2. The values shown by ● and ○ are obtained by measuring the resistivities of specimens whose θ_2 are 0° and 90° respectively.

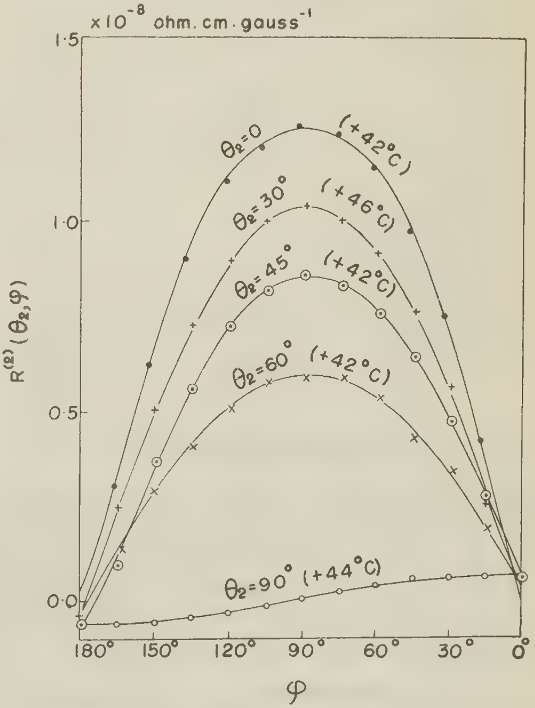

Fig. 4. φ-dependencies of $R^{(2)}$.

b) The components $R_{k,m}$ According to the method described in §2, the φ-dependency of $R^{(2)}(\theta_2,\varphi)$ given by Eq. (14) was measured and some of the results are shown in Fig. 4. It is evident that the square of the amplitude of the curves in Fig. 4 is given by $R_{1,1}^2\cos^2\theta_2+R_{3.3}^2\sin^2\theta_2$, which is the linear function of $\sin^2\theta_2$. This relation is shown in Fig. 5, from which the most probable value of $R_{1,1}^2$ may be found; on the other hand, the value of $R_{3.3}^2$ could not be found because the absolute value of $R_{3,3}$ is very small. But by inspecting the curves in Fig. 4 we can find that the sign of $R_{3,3}$ is probably opposite to that of $R_{1,1}$ and the absolute-value of the former seems to be as small as 1/20~1/30 of $|R_{1,1}|$. In Fig. 6 and Table I the temperature dependencies of $R_{1,1}$ and $R_{3,3}$ are shown.

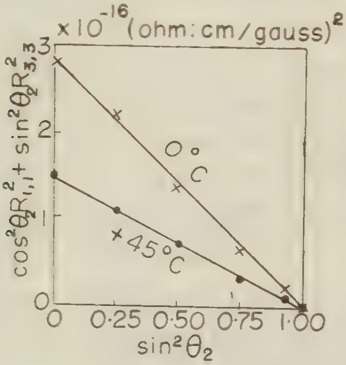

Fig. 5. Linear relation between the square of amplitude of $R^{(2)}$ and θ_2.

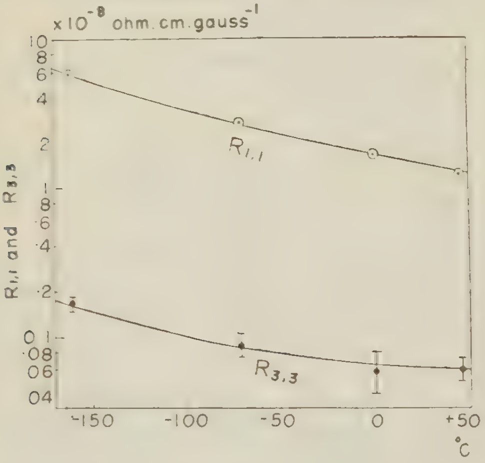

Fig. 6. Temperature-dependencies of $R_{1,1}$ and $R_{3,3}$.

c) **The components** $\rho_{ij,mn}$ By means of the first set of measurments, the values of $\rho_{11,11}$, $\rho_{11,33}$, $\rho_{33,11}$, $\rho_{33,33}$ and $\rho_{23,23}$ were found. The resistivity under various magnetic field strengths (H) and the directions (φ) of the magnetic fields were measured, and in Fi 7(a) is shown one of these results which r present the linear relation between the r sistance and H^2 at 45°C, and from this curv the value of $\rho^{(4)}(\theta_2,\varphi)$ for $\theta_2=0°$, $\varphi=90°$ obtained. As the temperature decreases, th range of the magnetic field where the linearli between the resistance and H^2 exists becom narrower, so at the liquid air temperature th measurements were performed for $H=0\sim2$

The unit: ρ_{ij} in ohm. cm.; $R_{k,m}$ in ohm. cm. gauss^{-1}; $\rho_{ij,mn}$ in ohm. cm. gauss^{-2}, $R_{k,mno}$ in ohm. cm. gauss^{-3}.

* at $+27._5$°C ** at −167°C : less accurate values

gauss. The φ-dependencies of $\rho^{(4)}(\theta_2, \varphi)$ were shown in Fig. 7(b), and may be expressed by the following equation:

$$\rho^{(4)}(\theta_2, \varphi) = A_0(\theta_2) + A_1(\theta_2)\cos 2\varphi + B(\theta_2)\sin 2\varphi \,. \tag{13'}$$

The accurate values of A_0, A_1 and B_1 may be found by means of numerical Fourier analysis*, and we have, for example,

$$\left.\begin{aligned} &A_0 = 1.8_1 \times 10^{-12}\ \text{ohm. cm/gauss}^2\,, \\ &A_1 = -0.9_7 \times 10^{-12}\ \text{ohm. cm/gauss}^2\,, \\ &B_1 = -0.22_5 \times 10^{-12}\ \text{ohm. cm/gauss}^2\,, \\ &(A_2 = -0.01 \times 10^{-12}\ \text{ohm. cm/gauss}^2\,, \\ &B_2 = -0.00_5 \times 10^{-12}\ \text{ohm. cm/gauss}^2.)^* \end{aligned}\right\} \tag{24}$$

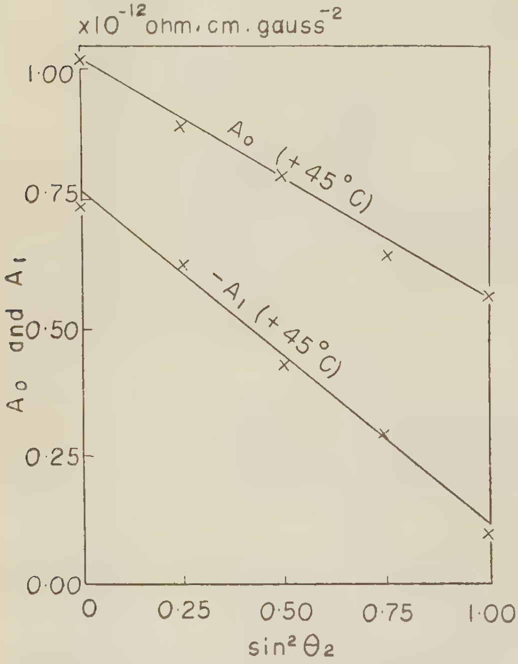

Fig. 8. Linear relation between θ_2 and A_0 or A_1.

for the specimen with $\theta_2=45°$ at 0°C. Therefore, if the θ_2-dependencies of A_0, A_1 and B_1 were found, it is easy to obtain the values of $\rho_{11,11}$, $\rho_{11,33}$, $\rho_{33,11}$, $\rho_{33,33}$ and $\rho_{23,23}$ from comparision of Eq. (13) and Eq. (13′) (see Fig. 8). Similarly, according to the second set of measurements for specimen whose θ_2 is 90°, one can easily find the values of $\rho_{11,23}$, $\rho_{11,22}$ and $\rho_{11,33}$; the last of which proves to agr with the value of $\rho_{11,33}$ obtained in the fir set of measurements within the experiment error. The only remaining component of t galvanomagnetic tensor is $\rho_{23,11}$, which determined by means of Eq. (18). All t values of $\rho_{ij,mn}$ and their temperature pendencies are shown in Fig. 9 and in Table

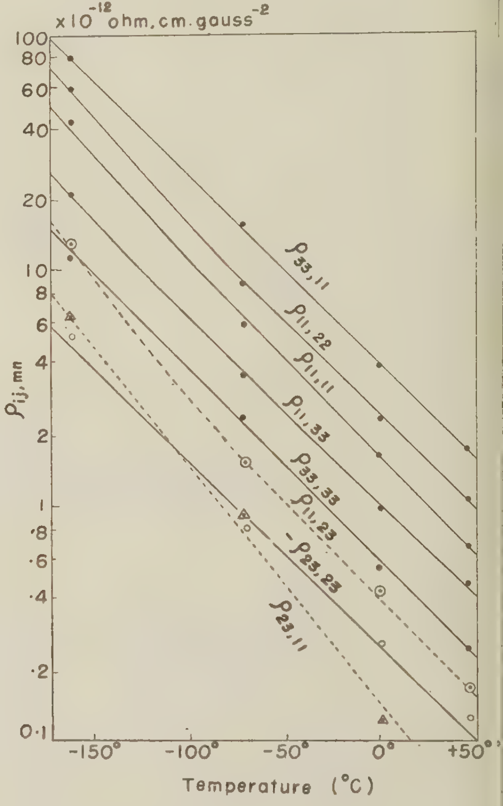

Fig. 9. Temperature-dependencies of $\rho_{ij,mn}$.

d) The components $R_{k,mno}$ According the third set of measurements, the odd pa of E_2/I_1' and E_3/I_1' were measured as functio of H, and by plotting $E_2/I_1'|H|\,vs H^2$ a $E_3/I_1'|H|\,vs H^2$ we can find the values $R_2^{(4)}(\theta_1)$ and $R_2^{(4)}(\theta_1)$ in Eq. (21) for vario values of θ_2. The results the three differe temperatures are shown in Fig. 10(a) and (b

---

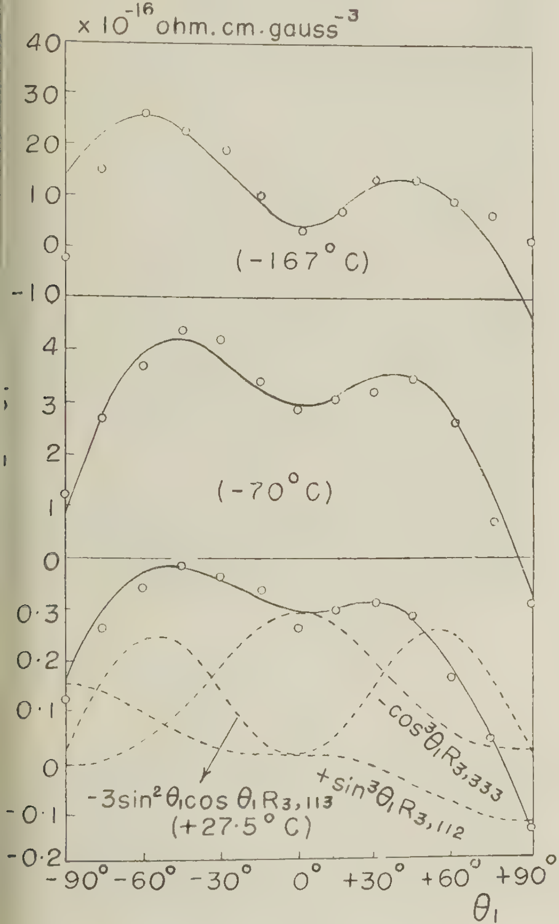
* The terms A_n and B_n ($n \geq 2$) in Fourier expansion

$$\rho^{(4)}(\theta_2, \varphi) = A_0 + \sum_n A_n \cos 2n\varphi + \sum_n B_n \sin 2n\varphi$$

proved to be as small as one percent of A_1 in most cases, so that we can assume that $\rho^{(4)}(\theta_2, \varphi)$ is represented by Eq. (13′).

* The applied magnetic field must be so sm that the curves $E_2/I_1'|H|\,vs H^2$ or $E_2/I_1'|H|\,vs$ remain linear; on the contrary if the field is t large these curves should bend, and then some e perimental errors would be introduced into $R_2^{(4)}($ or $R_3^{(4)}(\theta_1)$. In this work, we were obliged to app the magnetic field of 200~1500 gauss for specimen and this seems to be too strong at liquid air temp ature, so that the final results for this temperatu are considered to be less accurate than others.

By the analyses of these curves by means of Eqs. (21) and (23), six components of $R_{k,mno}$ are found and tabulated in Table I. Using these values of $R_{k,mno}$, $R_2^{(4)}(\theta_1)$ and $R_3^{(4)}(\theta_1)$ are recalculated and shown in Fig. 10(a) and (b) by solid curves. The dotted curves in the lower part of Fig. 10(a) are $-\cos^3\theta_1 R_{3,333}$, $-3\sin^2\theta_1\cos\theta_1 R_{3,113}$ and $\sin^3\theta R_{3,112}$, respectively, and the sum of them should be equal to $R_2^{(4)}(\theta_1)$ according to Eq. (21).



(a)

(b)

Fig. 10(b). Values of $R_3^{(4)}$ as function of θ_1. The calculated values are shown by solid curves, and the observed are shown by small circles.

§ 5. Discussion

Some components of the galvanomagnetic tensors were already measured by several investigators; and in Table I values measured by Abeles-Meiboom,[14] Vergler[4] and Stierstadt[5] are also listed. Values of components of the resistivity tensor and Hall tensor obtained by Abeles-Meiboom coincide with those of this work. As for the magnetoresistance tensor, their values of $\rho_{11,11}$, $\rho_{33,11}$ and $\rho_{11,22}$ are consistent with ours;* whereas our values of $\rho_{11,33}$ and $\rho_{33,33}$ are about two times larger than theirs.*,** The quantitative concordance between our values and Vergler's or Stierstadt's are not remarkable as shown in Table I.

Both components of the resistivity tensors

---

* From Fig. 9, values of components of the magnetoresistance tensor for 23°C are interpolated as follows:

$\rho_{11,11}=1.0_1\times10^{-12}$, $\rho_{11,33}=0.66\times10^{-12}$,
$\rho_{33,11}=1.9_6\times10^{-12}$, $\rho_{33,33}=0.37\times10^{-12}$
$\rho_{11,22}=1.5_2\times10^{-12}$.

** Values of $\rho_{11,23}$, $\rho_{23,11}$ and $\rho_{23,23}$ were not measured by Abeles-Meiboom.

ρ_{ij} increase linearly with the increasing temperature as shown in Fig. 3, and if the curve for ρ_{33} is extrapolated to lower temperatures it will intersect the abscissa at −256°C or 17°K. Therefore, roughly speaking, the resistance is proportional to the temperature except for the very low temperature region, and this temperature dependency has already been observed for pure bismuth by several authors.[15)] The order of magnitude of the resistivity is 10∼100 times greater than that of normal metals, because of very small concentration of the free carriers. The degree of anisotropy is not so large, as ρ_{33}/ρ_{11} is 1.2_7 at 45°C, 1.2_8 at 0°C, 1.3_1 at −60°C and 1.2 at −160°C.

Whereas the anisotropy of the Hall effect is very remarkable. The component $R_{1,1}$ which can be measured when the weak magnetic field is applied along x_1-(or x_2-) axis of the crystal, is positive* and amounts to 1.21×10^{-8} ohm. cm. gauss^{-1} at 45°C and becomes nearly five times greater at −160°C (cf. Fig. 6). But the absolute value of $R_{3,3}$, which is the Hall coefficient measured when the weak magnetic field is applied along x_3-axis, is very small (less than 5% of $R_{1,1}$), and its sign may be negative as described in the preceding section.

The transverse magneto-resistance effect for weak magnetic field relates to the components $\rho_{ij,mn}$, where the subscripts before the comma mean the direction of current, and the subscripts after the comma the direction of magnetic field. Among these components the following relation was observed:

$$\rho_{33,11} > \rho_{22,11} > \rho_{11,33} ,$$

and $\rho_{33,11}$ is about four times larger than $\rho_{11,33}$.**

The change of resistance in the longitudinal magnetic field will be estimated by $\rho_{11,11}$ and $\rho_{33,33}$, and the former is about three times larger than the latter; and it is noteworthy that "$\rho_{11,11}$ is larger than $\rho_{11,33}$", or the longitudinal effect is more remarkable than the transverse one in this case. On the whole, it can be said that the change of resistance is most striking when the field is applied along x_1-axis. The magnitude of the remaining components $\rho_{11,23}$, $\rho_{23,11}$ and $\rho_{23,23}$ are smalle than the others, and any intuitive interpretation can not be given for these components The temperature-dependency of $\rho_{ij,mn}$ is very noticeable, as is shown in Fig. 9; the value of $\rho_{ij,mn}$ at −160°C is about one hundred times larger than that at 45°C.

The galvanomagnetic tensor $R_{k,mno}$ is concerned with the field-dependency of the Hal coefficient. The components $R_{1,111}$ and $R_{3,33}$ are defined by the following equations:

$$\left.\begin{aligned} \frac{E_3}{I_1'H}&=R_{1,1}+R_{1,111}H^2 , \qquad (H//x_2\text{-axis}) \\ -\frac{E_2}{I_1'H}&=R_{3,3}+R_{3,333}H^2 , \qquad (H//x_3\text{-axis}) \end{aligned}\right\} \quad (25$$

where E_2 or E_3 is the electric field produced along x_3- (or x_2-) axis when the magnetic fiel is applied along x_2- (or x_3-) axis, and the current I_1' flow in the direction of x_1-axis. As shown in Table I, $R_{1,1}$ is positive, whereas $R_{1,111}$ is negative, so that the magnitude o $E_3/I_1'H$ becomes smaller as H increases. $R_{3,33}$ is also negative, but it is very small as compared with $R_{1,111}$.

From Table I, it is easy to see that the order of magnitude of various galvanomagnetic tensors at 45°C are given as follows:

$$\left.\begin{aligned} \rho_{ij}&\simeq10^{-4}\ \text{ohm. cm} , \\ R_{k,m}&\simeq10^{-8}\ \text{ohm. cm. gauss}^{-1} , \\ \rho_{ij,mn}&\simeq10^{-12}\ \text{ohm. cm. gauss}^{-2} , \\ R_{k,mno}&\simeq10^{-16}\ \text{ohm. cm. gauss}^{-3} , \end{aligned}\right\} \quad (26$$

neglecting the anisotropies of the each galvanomagnetic tensors. On the other hand, according to the formal theory of electronic conductors, the order of magnitude can be evaluated such as, if the anisotropy is neglected

$$\rho_{ij}\simeq\frac{m^*}{e^2}\frac{1}{n\tau}=\frac{1}{nec}\left(\frac{m^*c\omega_c}{e}\right) , \quad (27$$

where m^* is the effective mass of electron $\tau=1/\omega_c$ the collision time, and n the concentration of the free electrons. If one defines that

$$R=\frac{1}{nec} , \qquad H_c=\frac{m^*c\omega_c}{e} , \quad (28$$

Eq. (27) reduces to

$$\rho_{ij}\simeq RH_c . \quad (29$$

Similarly the order of magnitude for othe tensors can be estimated as follows[16)]:

$$R_{k,m}\simeq R , \quad \rho_{ij,mn}\simeq R/H_c , \quad R_{k,mno}\simeq R/H_c^2 . \quad (29$$

---

* The sign of $R_{i,i}$ is defined as positive for n-type conductor in this paper.

** Cf. Eqs. (28) of 16).

Comparing (26), (29) and (29′), we have

$$\left.\begin{aligned} R &\simeq 10^{-8}\ \text{ohm. cm. gauss}^{-1}, \\ H &\simeq 10^{4}\ \text{gauss}, \end{aligned}\right\}\ (\text{at } 45°\text{C}), \qquad (30)$$

from which the free electron concentration and the mobility are estimated as

$$\left.\begin{aligned} n &\simeq 6\times10^{19}\ \text{cm}^{-3} = 2\times10^{-4}\ \text{per atom}, \\ \mu &= \frac{e}{m^*}\frac{1}{\omega_c} \simeq 10^{4}\ .^* \end{aligned}\right\} \qquad (31)$$

In the actual bismuth, it may be necessary to consider electrons and positive holes simultaneously as discussed by Jones[17] and Abeles and Meiboom.[14] The results obtained in this work are now being analysed by applying the multi-ellipsoid theory of the galvanomagnetic tensors.[16]

The author wishes to express his sincere thanks to Prof. A. Okazaki for his kind encouragement and interest in this work. He is also indebted to Prof. Z. Miduno for his helpful advice about numerical Fourier analysis, and also to Messrs. K. Hirakawa, K. Hashimoto, S. Asanabe, A. Okazaki and H. Suzuki for their assistance in the measurements and for the preparation of specimens. This work was supported by the Scientific Research Expenditure of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 12, DECEMBER, 1957

Recombination of Excess Carriers in Semiconductors

By Jun'ichi OKADA

Matsuda Research Laboratory, Tokyo Shibaura Electric Co.,
Kawasaki-city, Japan

(Received August 22, 1957)

The recombination of excess carriers in semiconductors is discussed on the basis of a model in which the recombination occurs through multiple-levels. The theory is extended to apply to germanium. The dependence of carrier lifetime on temperature in most of pure n-type germanium samples can be explained by introducing two sets of traps, recombination centers ($E_C-E_r=0.30$eV) and hole trapping centers ($E_t-E_V=0.30$eV), in our temperature range. However, the minority carrier lifetime of samples containing comparatively high dislocation density (10^4-10^5/cm^2) is shown to vary with the dislocation density, and the results is expressed in terms of two lifetimes: τ_d, that associated with random dislocations, and τ_b, that due to the recombination centers of an undetermined origin. It is also shown that anomalous temperature dependence of the steady-state photoconductivity of high-resistivity p-type nickel doped germanium can be interpreted by assuming that two acceptor levels of nickel atom are effective at the same time, but different in the effect on the recombination process.

§ 1. Introduction

It is well known that in usual semiconductors the recombination of excess carriers is enhanced by lattice imperfections. These imperfections may introduce localized energy levels in the forbidden gap, which provide an intermediate step for recombination. We may call these localized levels as carrier traps. Shockley and Read[1] have discussed the hole-electron recombination rate resulting from the presence of only one set of such traps. However, in general there may be several different types of imperfections and an imperfection of each type may give several discrete energy levels[2]. Therefore it is necessary to consider the case where various sets of traps are effective. In the following we shall discuss the recombination through these multiple levels. The extension of simple theory to the case of multiple levels will first considered and then the experimental results for germanium will be compared with the extended theory.

§ 2. Theory

With the multiple-levels model we shall consider the rates of electron or hole transition between the traps and the conduction and valence bands owing to the processes which establish thermal equilibrium. Quantities which refer to localized levels or tra are given subscripts j, where different valu of j denote different levels.

Let R_{nj} and R_{pj} be the net rates of captu of free electrons and holes respectively by level. We can write

$$\left.\begin{aligned} R_{nj}&=\gamma_{nj}nN_j^+-g_{nj}N_j^-,\\ R_{pj}&=\gamma_{pj}pN_j^--g_{pj}N_j^+, \end{aligned}\right\}\qquad ($$

where γ_{nj} and γ_{pj} are the rates of capturi an electron and hole by a single j-trap, g and g_{pj} are the rates for converse processe n is the concentration of electrons in condu tion band, p is the concentration of holes valence band, and N_j^- and N_j^+ are the co centrations of j-traps occupied by electro and holes respectively. Here the relati between N_j^- and N_j^+ is given by

$$N_j^-+N_j^+=N_j\,,\qquad ($$

where N_j is the concentration of j-traps.

According to the principle of detail balance, $R_{nj}=R_{pj}=0$ in equilibrium. Ther fore,

$$\left.\begin{aligned} \gamma_{nj}n_0N_{j0}^+&=g_{nj}N_{j0}^-,\\ \gamma_{pj}p_0N_{j0}^-&=g_{pj}N_{j0}^+, \end{aligned}\right\}\qquad ($$

subscript 0 referring to the thermal equi brium condition. For nondegenerate sem conductors,

$$\left.\begin{aligned} n_0&=N_C\exp\{(F_0-E_C)/kT\}\ ,\\ p_0&=N_V\exp\{(E_V-F_0)/kT\}\ ,\end{aligned}\right\}\qquad(4)$$

and

$$\left.\begin{aligned} N_{j0}^-&=N_j(1+n_j/n_0)^{-1}=N_j(1+p_0/p_j)^{-1},\\ N_{j0}^+&=N_j(1+n_0/n_j)^{-1}=N_j(1+p_j/p_0)^{-1},\end{aligned}\right\}\qquad(5)$$

where N_C and N_V are the effective densities of states for conduction band and valence band respectively, F_0 is the Fermi level, E_C is the bottom energy of conduction band, E_V is the top energy of valence band, and n_j and p_j are the concentrations of free electrons and holes, respectively, when the Fermi level equals to the effective energy, E_j, of j-level. Thus, from (3), (4) and (5), we obtain

$$\left.\begin{aligned} g_{nj}/\gamma_{nj}&=n_j\ ,\\ g_{pj}/\gamma_{pj}&=p_j\ .\end{aligned}\right\}\qquad(6)$$

For small changes of carrier concentrations, denoted by Δn and Δp, lifetimes of electrons and holes are defined[*] by

$$\left.\begin{aligned} \tau_n&=\Delta n/\Delta R_n\ ,\\ \tau_p&=\Delta p/\Delta R_p\ ,\end{aligned}\right\}\qquad(7)$$

where $R_n=\sum_j R_{nj}$ and $R_p=\sum_j R_{pj}$.

Suppose that the disturbances in carrier concentrations are small enough that only first-order terms in Δn and Δp need be considered. From (1), (2) and (6), we get

$$\left.\begin{aligned} \Delta R_{nj}&=\gamma_{nj}\{N_{j0}^+\Delta n-(n_0+n_j)\Delta N_j^-\}\ ,\\ \Delta R_{pj}&=\gamma_{pj}\{N_{j0}^-\Delta p-(p_0+p_0)\Delta N_j^+\}\ .\end{aligned}\right\}\qquad(8)$$

Condition of electrical neutrality requires

$$\Delta n=\Delta p+\sum_j\Delta N_j^+=\Delta p-\sum_j\Delta N_j^-\ .\qquad(9)$$

As a further simplification, we shall limit ourselves here to steady-state condition,

$$\Delta R_{nj}=\Delta R_{pj}\ .\qquad(10)$$

In this case we have

$$\tau_p/\tau_n=\Delta p/\Delta n\ ,\qquad(11)$$

and Eqs. (8) and (10) give

$$\Delta N_j^+=-\Delta N_j^-=(\gamma_{pj}N_{j0}^-\Delta p-\gamma_{ni}N_{j0}^+\Delta n)/B_j\ ,\qquad(12)$$

where

$$B_j=\gamma_{nj}(n_0+n_j)+\gamma_{pj}(p_0+p_j)\ .$$

Substitution (12) into (9), we get

$$\Delta p/\Delta n=(1+H_p)/(1+H_n)\ ,\qquad(13)$$

where

$$\left.\begin{aligned} H_n&=\sum_j(\gamma_{pj}N_{j0}^-/B_j)\ ,\\ H_p&=\sum_j(\gamma_{nj}N_{j0}^+/B_j)\ .\end{aligned}\right\}$$

Hence, using (7), (8), (12) and (13), it is found that steady-state lifetimes are given by

$$\left.\begin{aligned} \tau_n&=(1+H_n)\,/\,\{n_0(1+H_p)+p_0(1+H_n)\}H\ ,\\ \tau_p&=(1+H_p)\,/\,\{n_0(1+H_p)+p_0(1+H_n)\}H\ ,\end{aligned}\right\}\qquad(14)$$

where

$$H=\sum_j(\gamma_{nj}\gamma_{pj}N_j/B_j)\ .$$

§ 3. Applications to Germanium

A. *Control Germanium Single Crystals*

In the case of control germanium samples known (from resistivity and lifetime measurements) to be high purity, it may be considered that

$$H_n \text{ and } H_p\ll 1\ .$$

Thus, from (14), we have single lifetime τ given by

$$1/\tau=1/\tau_n=1/\tau_p=\sum_j(1/\tau_j)\ ,\qquad(15)$$

where

$$\tau_j=\{\tau_{pj}(n_0+n_j)+\tau_{nj}(p_0+p_j)\}\,/\,(n_0+p_0)\ .\qquad(16)$$

Here τ_{nj} and τ_{pj} are the lifetimes defined by the equations

$$\tau_{nj}=1/(\gamma_{nj}N_j)\ ,$$

and

$$\tau_{pj}=1/(\gamma_{pj}N_j)\ .$$

Let us now consider the temperature dependence of τ.

Considering n-type samples ($n_0\gg p_0$), and assuming that the recombination centers lie in upper half of the energy gap ($n_j\gg p_j$), Eq. (16) reduces to

$$\tau_j=\tau_{pj}(1+n_j/n_0)\ .\qquad(17)$$

Thus, in the extrinsic region, at lower temperatures ($n_j\ll n_0$)

$$\tau_j\simeq\tau_{pj}\ ,$$

while at higher temperatures ($n_j\gg n_0$)

$$\tau_j\propto\exp\{(E_j-E_C)/kT\}\ .$$

This implies that, with decreasing temperature, τ_j decreases with the slope corresponding to (E_C-E_j) and reaches a plateau at lower temperatures. Temperature dependence of τ is given by substituting (17) to (15). In Fig. 1 we show in a qualitative fashion the dependence of τ_j and τ on temperature.

In order to test these results, we have measured the carrier lifetimes of control germanium samples as a function of temperature. Measurements were made by using experiment similar to that of Navon *et al.*[3)], wherein the time-decay of excess carriers injected electrically by a pulse is observed. Typical results on *n*-type germanium are shown in Fig. 2. In this figure, τ_R indicates the time constant of fast decay and τ_S is that of slow decay which follows the fast one These results are similar to that of Fan e *al.*[4)] Therefore we may conclude that τ_R and τ_S are accounted for by recombination and hole trapping centers respectively.

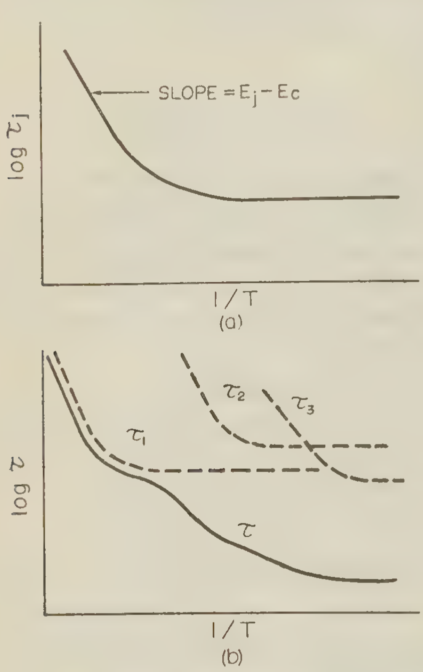

Fig. 1. The temperature dependence of lifetimes of control samples (qualitative only).
(a) τ_j *vs* $1/T$; (b) τ *vs* $1/T$.

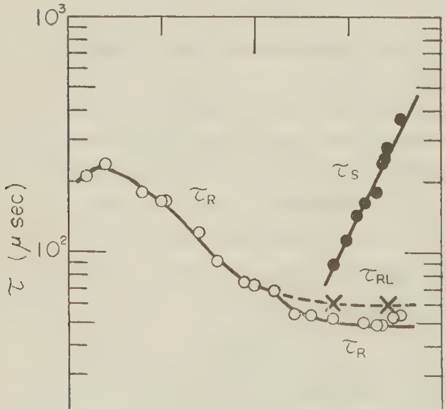

Fig. 2. Time constants τ_R and τ_S in 21 ohm-cm *n*-type germanium *vs* $10^3/T$.

We shall first consider τ_R. In this case we have two plateaus. This seems to mean that there exist at least two sets of recombination centers. However, as shown as dashed curve denoted by τ_{RL} in the figure, one of them can be removed by bias light. This is characteristics of trapping centers. Thus we can conclude that only one set of recombina tion centers is effective in our temperatu range and that the experimental curve ca be fitted by Eq. (17). Taking $\tau_{pr}=60\,\mu$ se and plotting $\log\{(\tau_R/\tau_{pr})-1\}$ *vs* $10^3/T$ give points shown in Fig. 3. Assuming E_C-E_r 0.30 eV, the calculated values of n_r/n_0 is als plotted in the figure, and is in good agre ment with the experimental data.

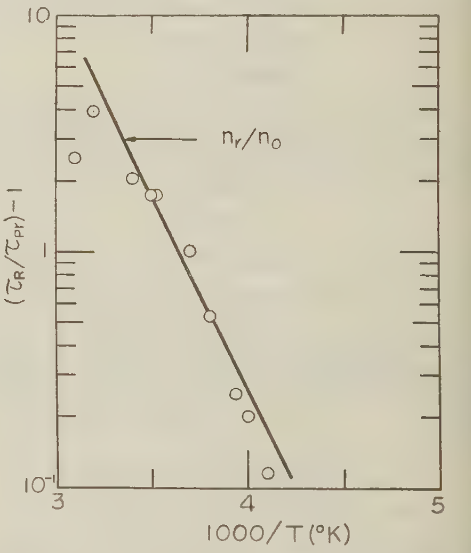

Fig. 3. $(\tau_R/\tau_{pr})-1$ *vs* $10^3/T$. The open circles ar experimental points and the solid line is plo of n_r/n_0.

We shall next consider the case where on one set of hole trapping centers is effectiv In this case, using the theory of trappin under transient conditions similar to that Fan[5)], we get

$$\tau_S \simeq 1/(\gamma_{pt}\,p_t)\,,$$

or

$$\tau_S \propto \exp\{(E_t-E_V)/kT\}\,,$$

and

$$1/\tau_R - 1/\tau_{RL} = N_t \gamma_{pt} ,$$

where suffix t denotes a trapping level. Using these relations, experimental data give $E_t - E_V = 0.30$ eV, $N_t = 8.4 \times 10^{11}/\text{cm}^3$ and $\gamma_{pt} = 3.4 \times 10^{-9}$ cm^3/sec.

On the other hand, when one set of recombination centers ($\gamma_{nr} \simeq \gamma_{pr}$) and one set of hole trapping centers ($\gamma_{nt} \ll \gamma_{pt}$; $B_r \ll B_t$) are effective, Eq. (14) gives two steady-state lifetimes,

$$\tau_n = \tau_{pr}\{1 + (N_t/p_t)\} ,$$

and

$$\tau_n = \tau_{pr} .$$

From these expressions, it follows that appreciable trapping effect occurs only when $N_t/p_t \geq 1$. Thus, using the experimental values of $E_t - E_V$ and N_t, we can calculate the critical temperature for hole trapping being the order of 200°K. This is in agreement with experiment. However, we cannot determine at this time what causes recombination or trapping centers.

B. *Recombination at Dislocations*

It has been shown that dislocations in and near the edge orientation act like rows of closely spaced acceptor centers with energies of about 0.2 eV below the bottom of conduction band in germanium[6]. Furthermore, unlike other imperfections, we have some methods to determine the dislocation density. Thus it is interesting to investigate the effect of dislocations on carrier lifetimes ingermanium. However, as mentioned above, in most of control samples the effect of other unknown imperfections predominates. Therefore, in order to distinguish the effect of dislocations, we must found a correlation between the lifetime and the dislocation density. When the dislocation density is not so high, this is done by using Eq. (15), and lifetime is given by

$$1/\tau = 1/\tau_d + 1/\tau_b ,$$

where τ_d is the lifetime due to dislocations and τ_b is the bulk lifetime due to the recombination centers of an undetermined origin. Let N_d is the density of randomly distributed dislocations per unit area and let ν is the number of traps per unit length of each dislocation. The concentration of dislocation traps is given by νN_d. For n-type samples,

$$\tau_d = (1/\gamma_{pd} \nu N_d)(1 + n_d/n_0) ,$$

because the level of dislocation traps lies in upper half of the energy gap. Then, if τ_b remains constant independent of dislocation density, plot of the inverse lifetime $1/\tau$ *vs* N_d should give a straight line.

We confirmed this relation in the following way.

Specimens for this investigation were selected from the single crystals of Sb-doped n-type germanium in 2.5 ohm-cm resistivity range. The dislocation density was determined by counting the etch pits[7]. Carrier lifetimes were obtained by the travelling light spot or Morton-Haynes method wherein the diffusion length of the minority carriers is measured[8].

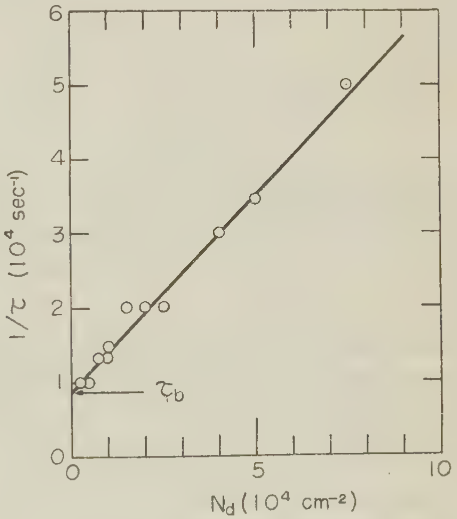

Fig. 4. Inverse lifetime as a function of dislocation density for 2.5 ohm-cm n-type germanium.

Experimental data are shown in Fig. 4, and the resulting straight line appears to prove our simple theory. The slope corresponds to $\gamma_{pd}\nu/(1 + n_d/n_0) = 5.5 \times 10^{-1}$ cm^2/sec, or $\gamma_{pd}\nu = 11$ cm^2/sec, if we take $E_C - E_d = 0.20$ eV. This is in good agreement with the value obtained from the measurements of the recombination velocity of minority carriers at the lineage boundary[9]. On the other hand, in order to obtain the values of γ_{pd} and ν separately, we must have the detailed knowledge of the electronic structure at a dislocation. Kurtz *et al.*[10] have discussed possible models by which the effect of dislocations on the recombination process might be explained. However, this is rather qualitative. Hence we do not know at this time by what means further analysis can be done.

C. *Nickel Doped Germanium*

Recently it has been found that some kinds of impurities each introduces several energy levels in germanium. Therefore such impurities can be expected to give the examples of the recombination through multiple-levels.

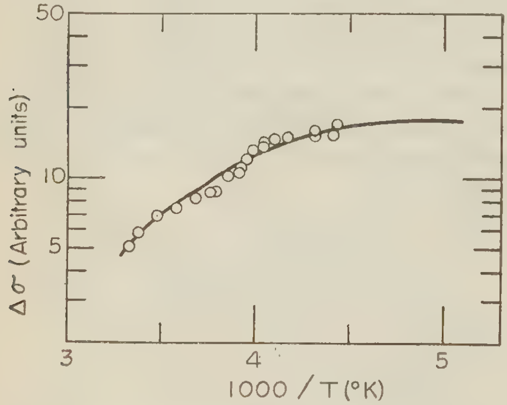

Fig. 5. Photoconductivity as a function of temperature for a high-resistivity *p*-type Ni-doped germanium. The open circles are experimental points and the solid line is calculated from Eq. (18).

However, the number of levels of each kind is not constant, but depends on the average degree of ionization of the impurities. Hence, in order to test the validity of our theory, it is necessary to use particular samples.

Experimentally we studied nickel as recombination center. Pure nickel was electroplated on originally *n*-type germanium samples. Then the samples were holded in nitrogen atmosphere at an appropriate temperature for such a time as to closely approximate the solubility limit of nickel in germanium throughout the sample[11]. This process permits us to control the concentration of nickel and the position of Fermi level. However, for reasons to be given below, among these samples, only the high-resistivity *p*-type samples were studied. Typical measurements of steady-state photoconductivity $\Delta\sigma$ are shown in Fig. 5. Results indicate that $\Delta\sigma$ increases with decreasing temperature but saturates gradually. Such a behavior of $\Delta\sigma$ is in contrast with that of control samples as shown in Fig. 6. This anomalous effect may be explained qualitatively by assuming that the capture cross-sections for free carriers are affected by charge distribution in nickel atom[12]. However, more quantitative explanation can be given in terms of multiple-levels model as follows.

It has been shown that nickel introduces two acceptor levels in germanium: one (upper level) at 0.30 eV below the bottom of the conduction band, the other (lower level) at 0.22 eV above the top of the valence band[13]. These levels are not always independent. The lower acceptor level is defined by placing an electron upon a neutral nickel atom, while the upper level is defined by placing an electron upon a singly charged (Ni⁻) ion. Thus the upper level when filled destroys the lower level. However, in the case of high-resistivity *p*-type nickel doped germanium, it is possible to assume that both levels are effective at the same time, because the Fermi level is so close to the lower level.

For our samples, the resistivity data shown in Fig. 7 indicate that

$$E_1 > (E_C + E_V)/2 > (E_1 + E_2)/2 > F_0 > E_2 \,,$$

and

$$N_1 = N_2 = N_t \,,$$

where subscripts 1 and 2 denote upper and lower levels respectively, and N_t is the concentration of nickel atoms. In this case, if $\gamma_{n1} \simeq \gamma_{p1}$ and $\gamma_{n2} \simeq \gamma_{p2}$, Eq. (14) gives

$$\tau_n = \tau_{n1} \,,$$

$$\tau_p = \{\tau_{n1} + \tau_{p1}(N_t/p_0)\} / \{1 + (N_t/p_2)\} \,.$$

Then the steady-state photoconductivity of these samples is

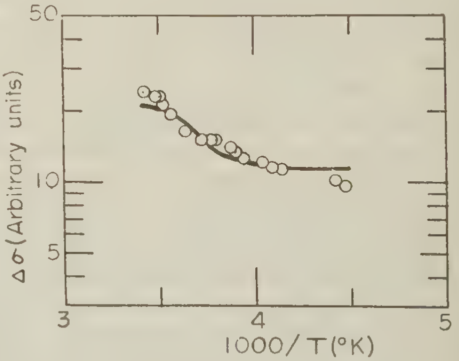

Fig. 6. Photoconductivity as a function of temperature for control *n*-type germanium (21 ohm-cm). The open circles are experimental points and the solid line is calculated from $\Delta\sigma = L\tau(\mu_n + \mu_p)$.

$$\begin{aligned}\Delta\sigma &= L(\tau_n\mu_n+\tau_p\mu_p)\\ &= L\tau_{n1}\,[\mu_n+\mu_p\{1+(\gamma_{n1}/\gamma_{p1})(N_t/p_0)\}\\ &\quad \div\{1+(N_t/p_2)\}]\,,\end{aligned} \tag{18}$$

where L is the rate of excitation and μ_n and μ_p are the mobilities of electrons and holes respectively. This implies that, at higher temperatures where $p_0<N_t<p_2$, $\Delta\sigma\simeq L\tau_{p1}\mu_p\times(N_t/p_0)$ or $\Delta\sigma\propto\exp\{(F_0-E_V)/kT\}$, and that, at lower temperatures where $p_0<p_2<N_t$, $\Delta\sigma\simeq L\tau_{p1}\mu_p(p_2/p_0)$ or $\Delta\sigma\propto\exp\{(F_0-E_2)/kT\}$. Since $F_0\simeq E_2$, Eq. (18), therefore, shows the expected temperature dependence. Quantitatively, it is necessary to know the values of parameters involved in Eq. (18). The values for N_t and p_0 are obtained from resistivity data, p_2 is calculated from Eq. (4) with $F_0-E_V=0.22$ eV, and the values of γ_{n1} and γ_{p1} can be estimated experimentally by comparing the effective lifetimes, defined by $\Delta\sigma/L(\mu_n+\mu_p)$, for two p-type nickel doped samples, where the value of L is determined by separate measurements at room temperature on a sample of known carrier lifetime. The solid curve in Fig. 5 is computed from Eq. (18) using the following parameters: $\gamma_{n1}=0.9\times10^{-9}$ cm^3/sec, $\gamma_{p1}=1.8\times10^{-9}$ cm^3/sec and $N_t=7\times10^{14}$/cm^3. The good agreement between the computed curve and the experimental data suggests that the model is valid, and shows that two acceptor levels of nickel are entirely different in the effect on the recombination process[14]. In the case of high resistivity p-type samples, most of excess holes are free at high temperatures and are trapped in the lower level at low temperatures, whereas most of excess electrons are trapped in the upper level and then recombine with free holes for all temperatures.

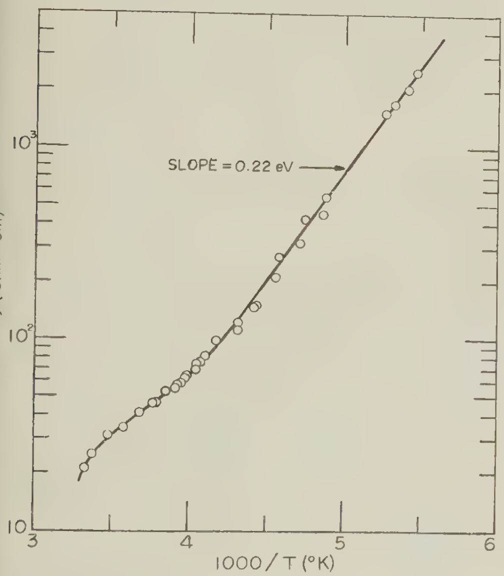

Fig. 7. Resistivity as a function of temperature for the sample of Fig. 5.

Furthermore, from the formula for Hall coefficient,

$$R=e(-C_n n\mu_n^2+C_p p\mu_p^2)/\sigma^2\,,$$

it follows that

$$\Delta p/\Delta n=[(C_n\mu_n+\delta)\,/\,(C_p\mu_p-\delta)]\,(\mu_n/\mu_p)\,,$$

$$\delta\equiv(R_L\sigma_L^2-R_0\sigma_0^2)\,/\,(\sigma_L-\sigma_0)\,,$$

where C_n and C_p are constants (Hall mobility/drift mobility) and subscripts 0 and L refer to dark and illuminated states respectively. This equation gives additional evidence for our interpretation. Experimentally we observed Hall coefficients and conductivities of our samples with and without a steady illumination. Taking $C_n=1.05$ and $C_p=1.85$[15], measurements for above sample give $\Delta p/\Delta n\simeq 3$. This is in good agreement with calculated value of 2.9. (Measurements for control samples give $\Delta p/\Delta n\simeq1$.)

Battey and Baum[16] have observed the similar temperature dependence of carrier lifetimes in nickel doped germanium. These results have been interpreted qualitatively in terms of variable cross-section model. However, even in this case, our theory may give another possible explanation.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 12, DECEMBER, 1957

An Electrical Resistance Study of the System $(Cr_xMn_{1-x})Sb$*

By Toshiro SUZUOKA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received August 22, 1957)

The temperature dependence of electrical resistance in the system $(Cr_xMn_{1-x})Sb$ was studied, which forms a homogeneous nickel-arsenide type solid solution of ferromagnetic MnSb and antiferromagnetic CrSb over the whole concentration range. It has been found that the resistance increases with rising temperature until it reaches a maximum at the Curie or the Néel point, and then it decreases. For the compounds with chromium concentration of $0.7 \leqq x \leqq 0.8$, another type of anomaly, that is, a small discontinuity of the resistance curve was observed at low temperatures. It is concluded that this anomaly may be attributed to the magnetic transition between ferrimagnetic and antiferromagnetic states, which was previously proposed to exist in this range of x.

§ 1. Introduction

The compound MnSb is a ferromagnetic substance with the Curie point at 310°C, while the compound CrSb is an antiferromagnetic one with the Néel point at 440°C. These two compounds, having the same crystal structure of the nickel-arsenide type, form a system of homogeneous solid solutions $(Cr_xMn_{1-x})Sb$ over the whole range of chromium concentration x. This system is known to show interesting magnetic behaviors[1]: if we substitute manganese atoms in the ferromagnetic compound MnSb with chromium atoms, the saturation moment decreases at first slowly ($x \leqq 0.1$) then falls rapidly with further substitution, and finally disappears at about $x=0.8$. Ferrimagnetism is expected, from the reciprocal susceptibility *vs* temperature curves, to prevail in the ranges of $0.1 \leqq x \leqq 0.8$. Also the Curie point lowers in a manner similar to the saturation moment (cf. Fig. 3). For the compound with $x=0.8$ (probably also with $x=0.9$), however, a type of antiferromagnetism appears in a temperature range above its ferrimagnetic Curie point. If we further increase the chromium concentration, this type of antiferromagnetism seems to become the typical one of CrSb, corresponding to $x=1$.

Such complicated magnetic behaviors may be explicable on the basis of the concept of triangular spin arrangement proposed by Yafet and Kittel[2]: a theoretical expectation[3] on a few reliable assumptions for the system showed good agreement with the experimental results concerning the relationship between the saturation moment and the concentration as well as that between the Curie point and the concentration. The theory further predicts that the magnetic transformation from ferrimagnetic to antiferromagnetic state would not be of the first order, hence it is expected that with such a transformation no appreciable anomaly would be observed in any physical properties, for instance, in electrical resistance, specific heat, etc. or it would be small if any. The primary purpose of the present investigation is to test this prediction through the measurement of the electrical resistance, which might also be of value in comprehending other physical proporties of these substances.

---

* This investigation was carried out at Prof. Hirone's laboratory in the Research Institute for Iron, Steel and Other Metals, Tohoku University, and was supported in part by the Grant-in-Aid of Fundamental Scientific Research of Ministry of Education.

§2. Experimental Results

The compounds to be measured were prepared by means of the ceramic method as described previously[1]. Namely, the mixtures of desired proportions of manganese, chromium and antimony powders below 100 mesh were sealed in evacuated silica tubes and were heated at temperatures somewhat below the melting points or the solidus line of the system for about 24 hours and slowly cooled down in the furnace. Reaction products thus obtained were powdered to 200 mesh or less and pressed into brickets of about 2×5×30 mm in size under the pressure of about 5 tons/cm^2, and then they were heated again by the same procedure as before.

These sintered samples were conductive enough to be measured by the potentiometric method; the resistivity at room temperatures was about 1×10^{-4} ohm-cm for MnSb and 3×10^{-4} ohm-cm for CrSb, while those for the intermediate compositions roughly lay between the terminal values. Connection of specimens with electrical leads, which were platinum wires of 0.15 mm in diameter, was made by welding with electric discharge from a condenser of 60 μF. The temperature range in which the measurements were made was that from the liquid nitrogen temperature to about 500°C, the maximum temperature being limited by the softening of the vacuum case made of S.B. glass.

The temperature dependence of the electrical resistance of the compounds $(Cr_xMn_{1-x})Sb$ is shown in Fig. 1, in which the magnitude of the resistance is represented by the ratio r/r_0, r_0 being that at 0°C. The sesistance of each compounds increases at first with increasing temperature, reaches a maximum at a certain temperature, and then decreases above it. Those critical temperatures, shown by downward arrows in the figure, accord with the magnetic Curie points observed previously[1]. Moreover, in the chromium-rich side we have found another type of anomaly or a small discontinuity which locates at 40°C for $x=0.7$, at 20°C for $x=0.75$ and at -60°C for $x=0.8$, as shown by upward arrows in the figure. This kind of anomaly is very small, say below 1%, as seen from an enlarged figure (Fig. 2). They are probably ascribed to the abovementioned transition between ferrimagnetic and antiferromagnetic states.

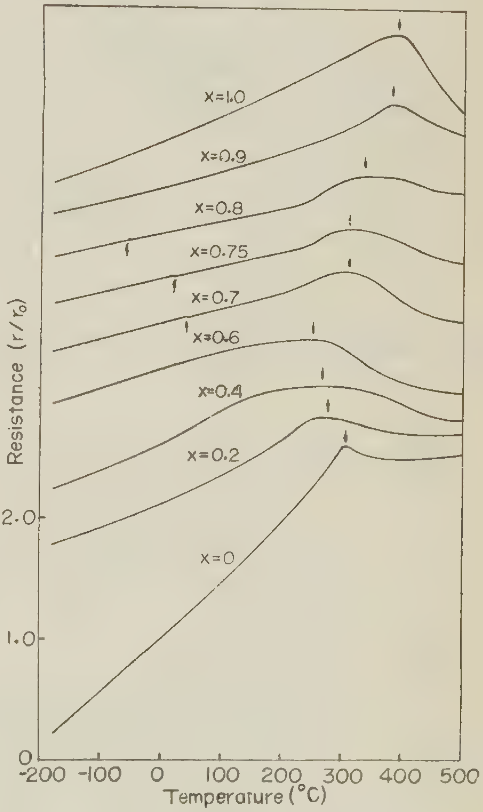

Fig. 1. Temperature dependence of the electrical resistance of $(Cr_xMn_{1-x})Sb$ system. The magnitude of resistance is represented by the ratio r/r_0, r_0 being that at 0°C. Resistance scale is indicated only for MnSb with $x=0$.

In Fig. 3, the temperatures of the anomalies (open circles) obtained from the resistance measurements are plotted against the chromium concentration x, and compared with the Curie points (full circles) found by the magnetic measurements referred to before[1]. The agreement between these temperatures is very good for low concentrations. As for CrSb as well as for compounds in the chromium-rich region, however, the agreement is not so good. The disagreement seems to be inherent in CrSb, since we have ascertained the difference between the Néel point (440°C*) as determined by the magnetic measurement conducted newly by the present author and the temperature (390°C) of anomaly found in the electrical measurement mentioned above.

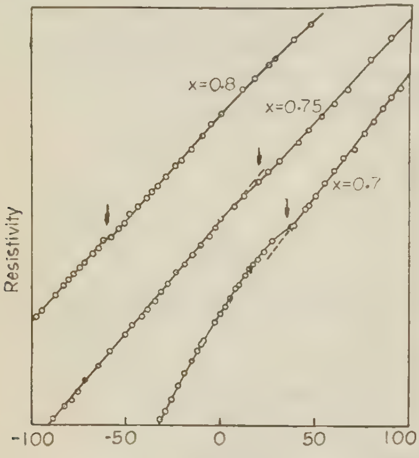

Fig. 2. Resistivity of the compounds with x from 0.7 to 0.8.

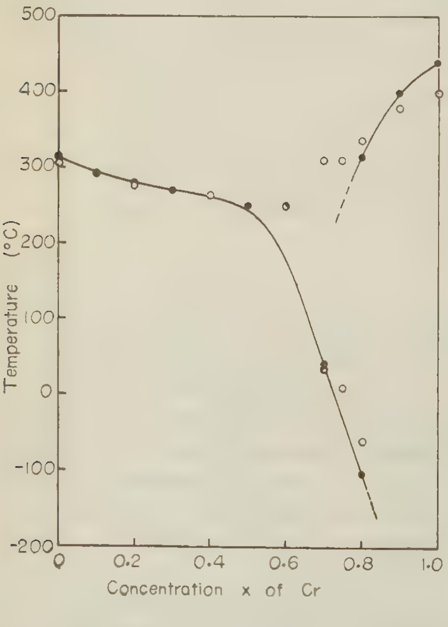

Fig. 3. Magnetic phase diagram of $(Cr_xMn_{1-x})Sb$ system. Full circles represent Curie points obtained from the magnetic studies[1], open circles those from the resistance measurements.

§ 3. Discussion

As mentioned above, the magnetic properties of this system may be explained on the basis of the idea of triangular spin arrangement that the resultant spin moments of different kinds of cations form an angular coupling due to the presence of various kinds of exchange interactions, which may be expected to exist in such a substitutional type of compounds with off-stoichiometric concentrations[3]. The angle between spin directions depends on the concentration since spin moments are affected by such exchange interactions; in the present case these interactions may be assumed to be ferromagnetic for a pair of Mn-ions as well as for a Mn–Cr pair while it may be antiferromagnetic for a pair of Cr-ions. Thus the ferromagnetism observed in the intermediate range of x is considered to be a special type of ferrimagnetism, in which the moments of cations partially compensate each other by the angular arrangement. It may also be pointed out that this tendency will be put forward with increasing temperature and at the ferrimagnetic Curie point the moments of cations wholly compensate each other. If it is the case here, in the compounds with $x=0.7\sim0.8$, the magnitude of the total spin moment of each sublattice will not change at the ferrimagnetic Curie point but only the interrelation between the directions of spins on different sublattices leads to the disappearance of the resultant moment. It will therefore be expected that on passing through the transition from one type of spin angular arrangement to another, appreciable energy change of the system will not occur. Thus at the transition temperature the specific heat will exhibit no anomaly, also the resistance as well. Of course the above picture is very crude one, and so the occurrence of a extremely small anomaly is not precluded. On the contrary, at the Curie points of the compounds on the manganese-rich side or at the Néel points of those on the chromium-rich side these physical properties will display large anomalous changes due to the disordering of spins. The result of our resistance measurements supports the above expectation.

---

* This temperature is in accord with that given in reference (1).

Finally, according to the present measurements of electrical resistance it seems that the antiferromagnetic region on the chromium-rich side extends towards somewhat more manganese-rich side than deduced from the magnetic measurements¹⁾, since at least for $x=0.7$ the antiferromagnetic region exists. In the previous measurement of magnetic susceptibility of the compound with $x=0.7$, the minimum in the reciprocal susceptibility *vs* temperature curve, which should be expected to appear for an antiferromagnetic, was not found, but instead there appeared only an inflexion point. The present measurement, however, demonstrates clearly that the substance has surely an antiferromagnetic state by the appearance of two anomalies in the electrical resistance, since these two anomalies should be of the same nature as those found in the specimens with larger chromium content.

In closing the author wishes to express his sincere thanks to Mr. S. Maeda and Dr. H. Watanabe for their encouragement and valuable discussions.

Lifetime Measurements of Minority Carriers Across and Along a Dislocation Wall in a Germanium Crystal

By Ryukiti R. HASIGUTI and Etsuyuki MATSUURA

Department of Metallurgy, University of Tokyo

(Received August 26, 1957)

Lifetime of minority carriers were measured across and along a dislocation wall in a *n*-type germanium crystal. The spacing of dislocations in the wall is about 2×10^{-4} cm. Recombination diameter of a dislocation in the dislocation wall is 2.2×10^{-8} cm. The lifetime is unusually large (about 210μ sec.), when it is measured along the wall. The usual value of lifetime is about 70μ sec. in this specimen. It is suggested that the dislocation wall forms a *p*-type thin layer in a *n*-type crystal.

§1. Introduction

Vogel et al.¹⁾²⁾ found a beautiful dislocation wall by means of etch pits technique in a small angle grain boundary in a germanium crystal. This kind of wall is precisely what the dislocation theory predicts. On the other hand it is known that the lifetime of minority carriers decreases when dislocations exist in germanium crystal.³⁾ It is expected, therefore, that the lifetime will be decreased, if the measurements are made across the wall which is made of dislocation array.

This was actually confirmed by several authors⁴⁾⁵⁾⁶⁾, but it is desirable at present to have more data in different conditions.

Experiments were carried out to obtain more data on this effect of dislocation wall. We also measured the lifetime along a dislocation wall, and obtained a very interesting and unexpected result.

§2. Observation of Dislocation Walls

Fig. 1 shows a dislocation wall, which was revealed by etching a germanium crystal by CP4 solution²⁾. The top and back faces of this crystal are {100} planes, and four side faces are {110} planes. The trace of dislocation wall on the top face (001) runs in [110] direction (Fig. 2). It was found by careful observations on top and back faces of the specimen that this wall penetrates through the whole thickness of the specimen (4 mm) from top face to back face, and it was also found that the wall is perpendicular to the top and back faces. This was also confirmed by the fact that the continuous etching of top face did not change the position and external appearence of the array of etch pits in the wall. Irregular network figure which is observed on both sides of the wall becomes faint and often disappears by changing the etching solution. For instance Fig. 3 shows the etch figure revealed by a modified CP4 solution and network figure is vanishingly faint. Incidentally the photograph in Fig. 3 suggests the structure of bottom of etch pits. It seems that the bottom has such a structure as shown in Fig. 4, when the direction of shadow is considered.

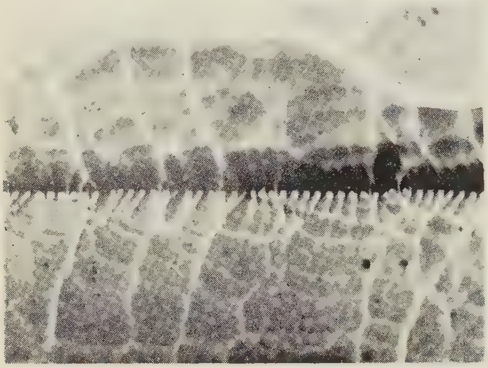

Fig. 1. A dislocation wall in a germanium crystal. Etched by CP4. Magnification: ×640.

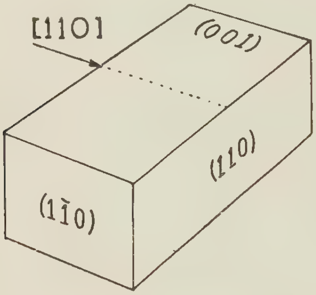

Fig. 2. Germanium crystal used.

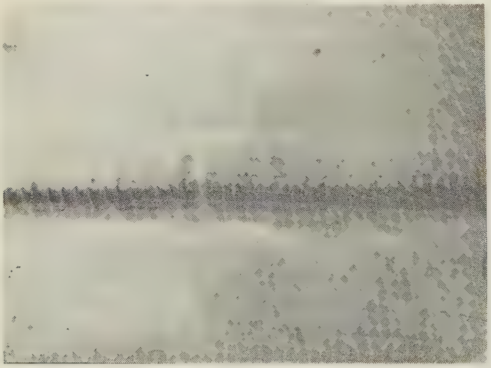

Fig. 3. The same dislocation wall as in Fig. 1. Etched by modified CP4. Magnification: ×900.

The next problem is to consider the direction of dislocation line. Vogel considers that the direction of dislocation lines is [001] in his specimen[2]. Although we did not use the X-ray measurement as Vogel did, we can conclude from the above mentioned surface observations and some other additional indirect evidences that the dislocation lines in our specimen may have one of the following two directions. These alternatives are:

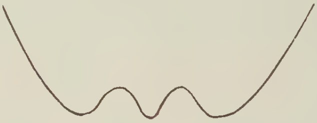

Fig. 4. Structure of the bottom of an etch pit. (Schematic).

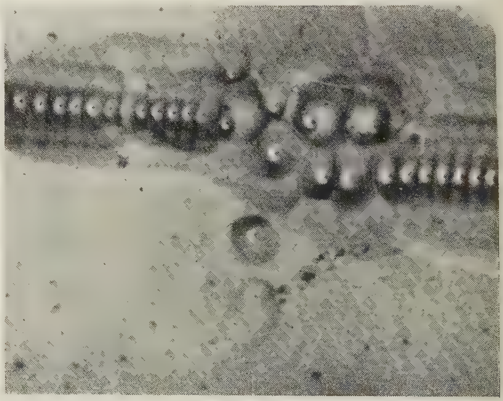

Fig. 5. A complex array of dislocations including doublets and triplets. Magnification: ×950.

(i) [001] edge dislocations with Burgers vector $a/2$ [$\bar{1}$10] in a slip plane {110}, and

(ii) [$\bar{1}\bar{1}$2] edge dislocations with Burgers vector $a/2$ [$\bar{1}$10] in a slip plane {111}.

In germanium, however, only {111} planes are known at present as slip planes from the experiments of plastic deformation, but {110} planes are not yet known as slip planes.

On the other hand a complex dislocation array was found in the extreme end portion of our dislocation wall as shown in the microphotograph of Fig. 5. This is an assembly of dislocation doublets and triplets as shown schematically in Fig. 6. Such stable arrangements of dislocations in doublets or triplets were calculated in simple cases by means of elastic theory of dislocation by Uemura[7)].

In our opinion dislocations have actually moved in the direction perpendicular to the dislocation wall in the formation process at high temperatures of such doublets and triplets. This means that our dislocations in the wall should be glissile (or glidable) dislocations. Therefore, if the slips in germanium are limited on {111} planes, our dislocations should be the $[\bar{1}\bar{1}2]$ dislocations. But if it is possible that {110} planes become slip planes, for instance at high temperatures near the melting point, it is also possible that our dislocations are [001].

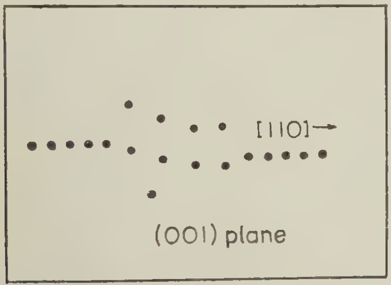

Fig. 6. A schematic representation of Fig. 5.

If we consider [001] dislocation lines, the spacing of our dislocation array is about 2.1×10^{-4} cm., and if we take $[\bar{1}\bar{1}2]$ dislocation lines, the spacing will be about 1.5×10^{-4} cm.

§3. Lifetime Across a Dislocation Wall

We obtained the recombination velocity v and the diameter g of the cylindrical recombination region associated with a dislocation (i.e., recombination diameter of a dislocation) from signals of Morton-Haynes' photo-injection method[8)] on both sides of the dislocation wall which was described in the preceding section. This is n-type germanium and its electrical resistivity is 2.5 Ωcm.

The results of measurements are shown in Fig. 7. The abscissa represents the distance between the photo-injection line and the collector probe, and the ordinate the collector voltage in arbitrary unit. From these measurements the recombination velocity was calculated by Vogel-Read-Lovell method[4)] to be

$$v=1.43\times10^3\ \text{cm/sec}.$$

From this value of v, the recombination diameter g is calculated[9)] as

$$g=2.2\times10^{-8}\ \text{cm}.$$

On the other hand it is admitted that the minority carrier lifetime τ in a germanium crystal with randomly distributed dislocations is correlated with the dislocation density N_d as follows:

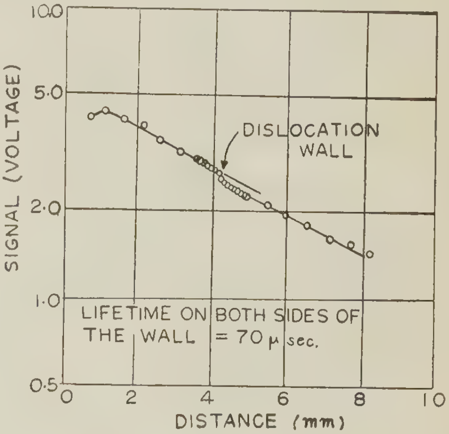

Fig. 7. Collector voltage vs light-probe distance. Measurement across the dislocation wall.

$$\tau=1/(N_d g\bar{c})\ ,$$

where $\bar{c}$ is the thermal velocity of minority carriers. Using the above value of g and 2.101×10^7 cm for $\bar{c}$[6)], we obtain

$$\tau=2.16/N_d.$$

This relation is plotted as a line (e) in Fig. 8.

In Fig. 8 data from different authors were plotted for comparison. The line (a) represents data from 4 Ωcm n-type crystal with uniformly distributed dislocations (Kurtz et al.[3)]); the line (b) shows the results from a dislocation wall in n-type germanium (McKelvey[6)]); the line (c) was plotted from the data of plastically deformed n-type crystals (Wertheim and Pearson[10)]); the line (d) represents the results from n-type crystals with randomly distributed dislocations (Okada[5)]). Okada's results from dislocation wall with

$g=2.3\times10^{-8}$ cm agree completely with our results (e).

Results obtained in our laboratory from 3~7 Ωcm n-type germanium with randomly distributed dislocations were also shown as open circles and crosses in Fig. 8. Here the dislocation densities were measured in two ways. Firstly only large etch pits with figures of concentric circles around the respective centers of etch pits were counted. These are expressed by open circles. Secondly all etch pits including small ones without concentric circles around them were counted. These are shown as crosses. The latter value seem to be closer to the real values of density. These measurements on τ and N_d were made on (100) planes of crystals.

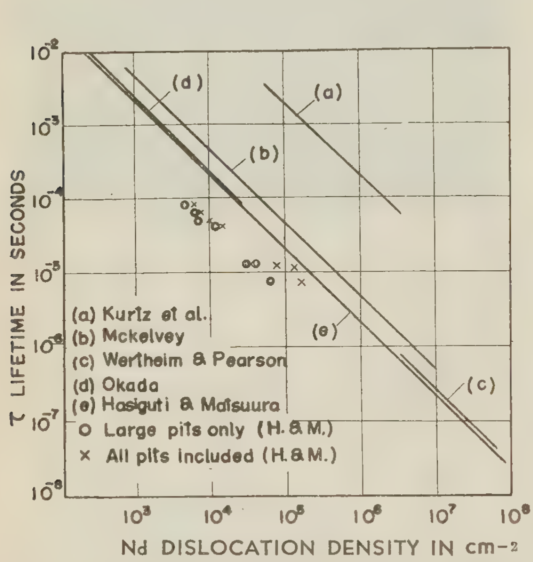

Fig. 8. Lifetime in n-type germanium vs dislocation densities.

It is considered that

$$\frac{1}{\tau}=\frac{1}{\tau_b}+\frac{1}{\tau_d},$$

where τ_b is the body lifetime due to recombination centers other than dislocations and τ_d is the lifetime due to randomly distributed dislocations. Using the data shown as crosses in Fig. 8, τ_b is calculated by Okada's method[5] to be

$$\tau_b=153\ \mu\text{sec}.$$

Using this value of τ_b, we obtain values of τ_d from the values (crosses) in Fig. 8. These τ_d's as a function of N_d's agree quite well with our plot from dislocation wall (the line (e) in Fig. 8).

§ 4. Lifetime Along a Dislocation Wall

A very interesting result was obtaine when the measurements were made puttin the collector probe on the dislocation wall As shown in Fig. 9 A, we found a very lon lifetime, which is 210 μsec., when photo injection site is moved along the dislocatio wall. In Fig. 9 B, the results are show when photo-injection line was moved perpendicularly to the wall. The lifetime is 70 μ sec which is the same as was found on bo sides of the wall in the preceding sectio (Fig. 7).

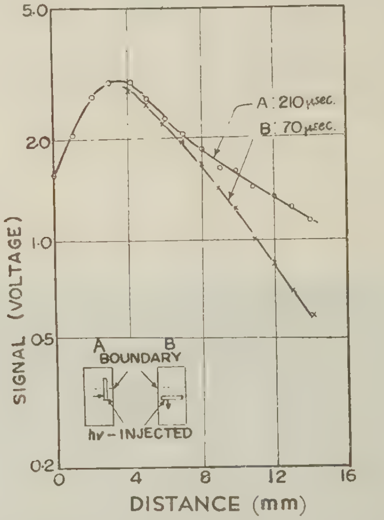

Fig. 9. Collector voltage vs light-probe distance.
(A) Measurement along the dislocation wall.
(B) Measurement perpendicular to the dislocation wall.

It is interesting and important that a ver long lifetime is found when the measurements are made along the dislocation wall It is supposed that this phenomenon is du to the same mechanism which gives rise t the fictitious long lifetime in a germaniu crystal with alloy junction on the surface[11].

In our experiment the dislocation wall i considered to form a p-type thin layer whic results in a p-n junction. Thus it is conceivable that our dislocation junction gives ris to a long lifetime just as the alloy junctio does. In another paper[12], we shall repor the effect of deuteron irradiation on th surface of germanium crystal. Again fictitious long lifetimes were found. It is interesting to note that the lattice defects produce by deuteron irradiation also form a p-type thin layer in an n-type crystal.

§ 5. Summary

1. Observations were made on a dislocation wall in a germanium crystal.

2. Recombination diameter of a dislocation in a dislocation wall was measured in n-type germanium. It is 2.2×10^{-8} cm. From this value a relation between lifetimes and densities of randomly distributed dislocations was obtained which agrees fairly well with experimental results of other authors.

3. Minority carrier lifetime is unusually long (fictitiously long), when it is measured along a dislocation wall. This seems to show that the wall forms a p-type layer.

Acknowledgement

The authors' thanks are due to Prof. Y. Uemura for his valuable discussions and to Tokyo Tsushin Kogyo, Ltd. for supplying them with germanium specimens. The expense for this research has been partly defrayed by the Scientific Research Grant from the Ministry of Education.

Lifetime Measurements of Minority Carriers in Deuteron Irradiated Germanium Crystals

By Ryukiti R. HASIGUTI, Etsuyuki MATSUURA
and Shiori ISHINO
Department of Metallurgy, University of Tokyo

(Received August 26, 1957)

Minority carrier lifetimes were measured on the deuteron irradiated surfaces of n-type germanium crystals. Fictitiously long lifetimes were obtained which suggest the formation of a p-type thin layer by the deuteron irradiation. Etch figures were observed on the irradiated surfaces.

§ 1. Introduction

Studies of radiation damage in germanium crystals have been carried out by K. Lark-Horovitz and his coworkers[1] and many others in recent years. It has been recognized that the irradiation of germanium crystals by high energy particles produces lattice defects which act as acceptors in n-type germanium, and that n-type germanium is converted into p-type by prolonged irradiation.

Fast neutron irradiation may produce a homogeneous distribution of lattice defects, which may be relatively easy to analyse. In the case of charged particle irradiation, however, the analysis of results may be very difficult, because the distribution of produced defects must be heterogeneous on account of short range of charged particles in germanium crystals. Nevertheless we can expect some kinds of interesting phenomena in the case of charged particle bombardment. For instance a number of lattice defects may concentratively be produced around the place where bombarding particles come to standstill and, therefore, a thin *p*-type layer may be formed in a *n*-type germanium crystal. The aim of this study is to explore such kinds of problems.

§ 2. Experimental Procedure and Results Obtained

Specimens used were *n*-type germanium crystals with more than 30Ω cm resistivity, cut into slabs with dimensions of about 1.5 ×4×10 mm, polished and etched by CP4 solution[2]. They were irradiated by deuterons from a cyclotron at Scientific Research Institute (Tokyo). After irradiation, lifetimes of minority carriers were measured on the irradiated surface by photo-injection method developed by Morton-Haynes[3]. Then the irradiated surface was etched off little by little by modified CP4 solution (CH_3COOH increased), and lifetimes were determined on every stages of etching. Depths from the initial surface were measured by means of a microscope and a micrometer.

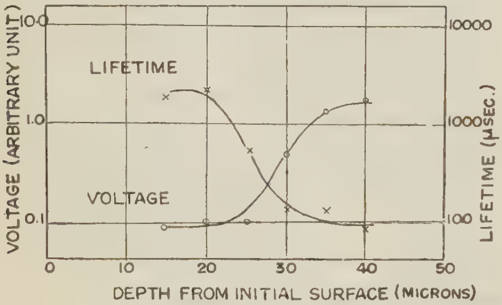

Fig. 1. Lifetime and maximum collector voltage as a function of depths from the initial surface in a deuteron irradiated n-type germanium. Irradiated at room temperature. Measurements 830 hr. after irradiation.

Fig. 1 shows the results obtained as a function of depths from the initial surface. In this case the specimen was placed outside the cyclotron window in the atmosphere at room temperature, and was irradiated by 2 MeV deuterons. The irradiation dose was 1.1×10^{16} deuterons/cm². Measurements of lifetimes were started 830 hours after the irradiation.

As shown in Fig. 1 the lifetime is unusually long at the initial surface after irradiatio It is sometimes larger than 2000 μsec. A the surface layer is etched off, the lifetim decreases gradually and restores its origina value (before irradiation), when about 40 μ the surface layer were removed. This valu of depth is about the same as the range deuteron in germanium.

When the photo-injection line falls on th same position as the collector probe, the co lector voltage comes to a maximum, of whic the plot is given also in Fig. 1 as a functio of the depths from the initial surface. Th maximum voltage is proportional to the phot current collected at the negative probe. I is very small (i.e. only 2 ∼ 3 times as larg as the noise level) at the initial surface an increases as the surface layer is etched off The maximum voltage seems to show a pea just before it restores the original value (Fig 2).

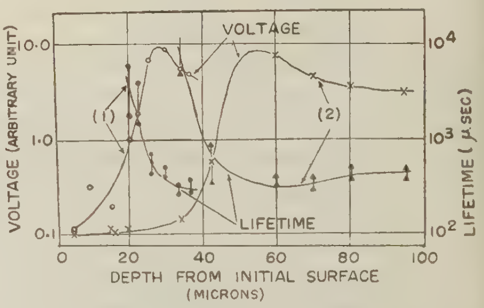

Fig. 2. Lifetime and maximum collector voltage as a function of depths from the initial surface in a deuteron irradiated n-type germanium. Irradiated at liquid oxygen temperature. (1) Measurements 26 hr. after irradiation. (2) Measurements 190 hr. after irradiation.

In the case of Fig. 2 germanium specimen were placed in vacuum inside the cyclotron and were irradiated by 3 MeV deuterons while being cooled by liquid oxygen. Irradiation dose was 5.8×10^{15} deuterons/cm². Lifetime measurements were carried out at room temperature. Two sets of curves correspon to different specimens. Curves (1) show set of observed results, of which the measurements were started 26 hours after the irradiation. Another set of measurement (curves (2)) were started 190 hours after th irradiation. Curves in Fig. 2 are much th same as those in Fig. 1 in their general ten dencies, but the peaks of maximum voltages appear clearly in Fig. 2.

A schematic representation of the collector voltage in an irradiated *n*-type specimen as a function of light-probe distance is shown in Fig. 3. Both ends of the specimen were covered by lead to make them free from radiation damage, thus corresponding maxima of collector voltage are found. Our model of the deuteron irradiated crystal which contains a *p*-type thin larger is shown in the lower part of Fig. 3.

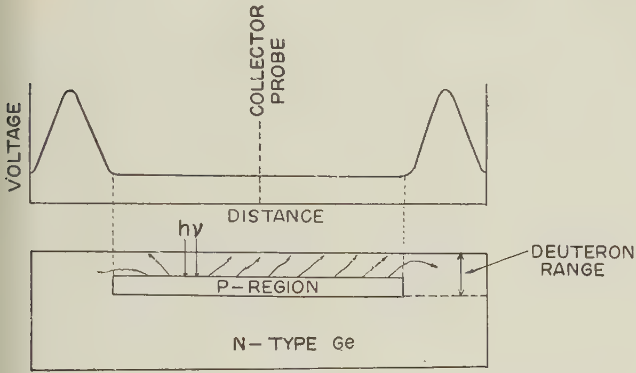

Fig. 3. Upper figure: a schematic representation of the collector voltage in a deuteron irradiated n-type germanium as a function of light-probe distance. The collector probe is at the center of the specimen. Lower figure: our model of irradiated specimen.

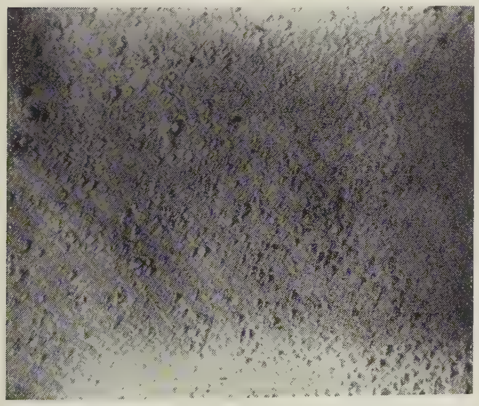

Fig. 4. Etching figure on {110} surface of germanium two days after irradiation. Etched by CP4 solution. Magnification: ×560.

The chemical etching figures of deuteron irradiated specimens were also observed. Although etching by CP4 solution does not usually exhibit any dislocation pit on {110} surfaces of germanium crystals, a great number of pit-like patterns were found on {110} surfaces of deuteron irradiated crystals. Irradiation dose used were about $10^{15} \sim 10^{16}$ deuterons/cm^2. Figs. 4 and 5 show these patterns. They are likely to be pyramidal etch hillocks rather than etch pits as they look. The microphotograph of Fig. 4 was taken two days after irradiation and Fig. 5 nine months after irradiation. Hillocks in Fig. 5 have grown to the size much greater than those in Fig. 4. These hillocks disappear, when the radiation damaged layer is etched off.

§ 3. Discussion of the Results

It is well known that a number of acceptors are formed in a germanium crystal, when it is irradiated by high energy particles, and a *n*-type crystal is converted into a *p*-type, if the irradiation is continued. It is expected, therefore, that a thin *p*-type layer will be formed within the range of deuteron in our *n*-type germanium.

Moore and Webster[4] measured the lifetimes in a germanium bar with alloy junction on back surface, and obtained fictitiously long lifetime. Our radiation-damaged specimen has a *p*-type thin layer under the irradiated surface, which acts just in the same way as Moore-Webster's alloy junction. The fictitious lifetime effect of irradiated surface decreases, when the surface is etched off gradually, as shown in Figs. 1 and 2. The effect disappears completely, when the surface layer is removed to the depth of about 40∼50 μ which is the same order of magnitude as the deuteron range in

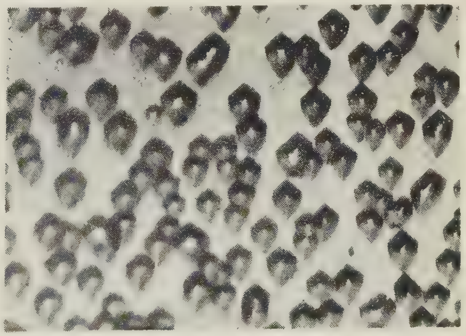

Fig. 5. Etching figure on {110} surface of germanium nine months after irradiation. Etched by CP4 solution. Magnification: ×320.

germanium. The peak of maximum voltage which appears just before it restores its initial value (Fig. 2) seems to correspond to intrinsic region of semiconductor.

The distribution of acceptors in the irradiated layer is not yet known. It is supposed that the density of acceptors will increase towards the end of deuteron range, because the cross section of displacement collision increases as the deuteron energy decreases.

A shift of curves is found between the two sets of curves in Fig. 2. This shift may be due to the difference in annealing time at room temperature after irradiation at liquid oxygen temperature. The difference in irradiation temperature seems also to affect the shape and position of the depth curve. Further investigations on these problems are being continued in our laboratory.

In another paper⁵⁾, we have reported that a dislocation wall forms a *p*-type thin layer, and unusually long lifetimes are obtained, when measurements are made along the dislocation wall. This phenomenon seems to be similar to the fictitious lifetime effect on the deuteron irradiated germanium surfaces which was reported in this paper.

§ 4. Summary

1. Minority carrier lifetimes were measured on the deuteron irradiated surfaces of *n*-type germanium crystals as a function of etched off depths from the initial surfaces.

2. Fictitiously long lifetimes were obtained which suggest the formation of a *p*-type thin layer in a *n*-type crystal by deuteron irradiation.

3. Etch figures were observed on the deuteron irradiated surfaces.

Acknowledgement

The authors wish to express their sincere thanks to Dr. A. Sugimoto for his kind guidance in using the cyclotron and to Tokyo Tsushin Kogyo, Ltd. for supplying them with germanium specimens. The expense of this research has been partly defrayed by the Government Atomic Energy Development Expenditure granted through the Japan Society for the Promotion of Scientific Research.

Electronic Structure of Simple Homonuclear Diatomic Molecules
II. Lithium Molecule

By Eiichi ISHIGURO,
Department of Physics, Ochanomizu University
Kunihusa KAYAMA, Masao KOTANI, and Yukio MIZUNO
Department of Physics, University of Tokyo

(Received August 3, 1957)

Based on LCAO MO CI method, the wave functions of Li_2 in the ground state $^1\Sigma_g{}^+$ and three lower excited states $^3\Sigma_u{}^+$, $^1\Sigma_u{}^+$, and $^1\Pi_u$ are calculated non-empirically. Calculation is performed at internuclear distances of 4.5, 5.0 and 5.5 a.u. by use of $1s$, $2s$, and $2p$ atomic orbitals of Stater type. Further, for the ground state, various approximations are investigated. Among other results, it is to be noted that HL method gives a lower total energy than MO method, and that in CI wave function a configuration corresponding to π-bond appears with an unexpectedly large coefficient. By using these wave functions depth of adiabatic potentials, dissociation energy, and vertical excitation energies are calculated and compared with the observed values. Further, molecular quadrupole moment, gradient of the electric field at each nucleus, and oscillator strengths are calculated. It is found that, in general, CI improves appreciably the values of these quantities calculated by the single configuration. Some of our wave functions are analysed by the population analysis method developed by Mulliken. Finally, we have examined to what extent the virial theorem is satisfied by the present wave functions and the reason for the disagreement is discussed.

§ 1. Introduction

The present paper constitutes the second part of our series, and is devoted to the investigation of the lithium molecule, Li_2. The reason why this particular molecule was chosen as subject for study was already explained in part I$^{1)}$; we note here that the lithium molecule is the simplest molecule for which the effect of inner shell electrons can be studied and for which s-p hybridization, mixing of configurations involving π orbitals, etc., become important.

Many years ago, Bartlett-Furry$^{2)}$ and Rosen-Ikehara$^{3)}$ already treated this molecule by completely shrinking the $1s$ electrons into the respective nuclei and using Slater's nodeless AO, $2s$, for valence electrons, and they obtained satisfactory results for the dissociation energy. Later, however, James$^{4)}$ carried out an elaborate calculation using a variational wave function, taking inner shell electrons into account, and he showed that the shrinking method can hardly be justified.

In this paper we investigate this molecule from the standpoint somewhat different from James', that is, by LCAO MO CI method. Configurations involving π orbitals, which were not taken into account in James' calculation, are included in our calculation. Further, we carry out similar calculations for the lower excited states $^3\Sigma_u{}^+$, $^1\Sigma_u{}^+$, and $^1\Pi_u$ of this molecule, and various physical quantities are evaluated.

§ 2. Parameters used and Method of Calculation

Calculation has been performed with three sets of parameters (α, β), where $\alpha=\delta_1 R$ and $\beta=\delta_2 R$, δ_1 and δ_2 being orbital exponents of Slater AO's (I, (1)) and R being the internuclear distance. These sets of (α, β) are denoted by I, II, and III, and the values of

Table I. Sets of parameters.

Set / α, β	I	II	III
α	14.00	13.25	14.00
β	3.00	3.25	3.50

Table II. Values of orbital exponents δ_1 and δ_2.

Set	I		II		III	
R \ δ	δ_1	δ_2	δ_1	δ_2	δ_1	δ_2

5.5	2.54545 45	0.54545 45	2.40909 09	0.59090 91	2.54545 45	0.63636 36

them are shown in Table I. For each set, further, R is chosen, as 4.5, 5.0, and 5.5. a.u., on the by consideration that the equilibrium internuclear distance of the ground state ${}^1\Sigma_g{}^+$ is 5.05 a.u. The values of δ_1 and δ_2 corresponding to these values of α, β, and R are shown in Table II. These values are to be compared with 2.70 and 0.65 a.u., respectively, given by Slater's rule.[5)]

Tacle III. Values of coefficients α_{ij}, β_{ij}, γ_g and γ_u in Schmidt-OMO.[a)]

β_{32}	2.77957 82	2.10767 48	1.63550 15
β_{33}	1.98685 46	1.72124 92	1.52334 76
γ_u	0.58360 93	0.59394 58	0.60408 47

a) See Eq. (I, (3)).

As in the case of O_2, Schmidt-OMO's (I, (3)) are constructed from symmetry orbitals (I, (2)) expressed in terms of AO's. The values of coefficients α_{ij}, β_{ij}, γ_g, and γ_u of symmetry orbitals in Schmidt-OMO's depend on α and β but not on R. These values are shown in Table III.

The values of molecular integrals involving Slater type AO's [6)7)] and also Schmidt-OMO's[8)] were calculated rigorously and were already published.

Among ten Schmidt-OMO's, σ_{1g} and σ_{1u} orbitals, which are constructed from AO's $(1s)_a$ and $(1s)_b$ only, have much lower orbital energies than the others. Therefore, four electrons out of all the six are assumed here to occupy these orbitals and to form the ion cores. The remaining two electrons may be considered valence electrons. Next to σ_{1g} and σ_{1u}, σ_{2g} and σ_{2u} are supposed to have lower energies. With the use of these two orbitals besides the core orbitals, we can obtain the ground state ${}^1\Sigma_g{}^+$ and two lower excited states, ${}^1\Sigma_u{}^+$ and ${}^3\Sigma_u{}^+$. Among them two singlet states are observed spectroscopically, together with ${}^1\Pi_u$ state. In this paper we shall study these four states.

Tablel. IV. Configurations[a)] used in CI calculation for ground state ${}^1\Sigma_g{}^+$.

a) See the footnote a) of (I, Table IV).

Following the procedures explained in I, primitive functions for each state are constructed from products of Schmidt-OMO's and then configurational wave functions are set up by antisymmetrizing products of these primitive functions and spin functions. In primitive functions unpaired orbitals are written first, followed by paired ones (for example, (I, (8)).

For each type of symmetry, the configurations are denoted, by A, B, C, ...*, in which

---

* A, B, C, ... are denoted by 1′ 2′ 3′ ... in references (8) and (9).

Table V. Coefficients c_i's[a] of configurations in normalized wave functions and energies E's obtained by using eight configurations, together with energies E_0's obtained by single configurations A's and with energy depressions $|\Delta E| = |E - E_0|$ for $^1\Sigma_g^+$ state.

a) Covalent structure.

b) Ionic structure.

A may be taken as the configuration with the lowest energy.

Formulae[9] and numerical values[8] of all the required matrix elements for these configurations were derived following the method explained in I and were already published elsewhere.

§ 3. Calculation of Energy of the Ground State $^1\Sigma_g^+$.

We can construct eight configurations with $^1\Sigma_g^+$ symmetry from ten kinds of Schmidt-OMO's on the assumption that 1*s* electrons form closed shells. These configurations are listed in Table IV.

The single configuration A corresponds to the usual antisymmetrized orthogonalized molecular orbital wave function (ASOMO) built from linear combinations of atomic orbitals (LCAO). The total energies obtained by this approximation are shown in Table V as E_o for each values of α, β, and R.

Further, taking all the eight configurations into accounts, we have performed variational calculations for each set and each R. The resulting coefficients c_A, c_B, ... in the normalized wave function and the total energy E are given in Table V. The energy depression due to CI, $|\Delta E|=|E-E_0|$, is also listed in the same table.

Now these wave functions can be written also in terms of various structures in HL scheme, and the results are shown in Table VI. For convenience, we denote the normalized covalent and ionic structures built from two AO's x and w of valence electrons, as x–w and xw–, respectively. Thus, for example, $\mathring{s}$–σ and $\mathring{s}\sigma$– mean the normalized wave functions built from the primitive functions, (normalization constant) $\times\{(2\mathring{s}_a)(2p\sigma_b)+(2\mathring{s}_b)(2p\sigma_a)\}\times(1s_a)^2(1s_b)^2$ and (normalization constant) $\times\{(2\mathring{s}_a)\times(2p\sigma_a)+(2\mathring{s}_b)(2p\sigma_b)\}(1s_a)^2(1s_b)^2$, respectively. Interpretation of the coefficients in Table VI, however, is to be given with special caution because the structural wave functions form an *oblique* coordinate system. The relative instability of the coefficients with respect to the change of R and δ, as compared with the case of expansions in MO scheme, is also due to this obliqueness of the coordinate system. (See Tables V and VI.)

From Table V, we see that the total energy E obtained for Set II and R=5.0 a.u. is the best of all. Accordingly for this set and

we have investigated 22 different approximations, Case 1—Case 22, similar to those considered in I, § 4. Each of these 22 "cases" corresponds to a more or less restricted CI, and the resulting wave function (characterized by expansion coefficients in terms of normalized wave functions for configurations given in Table IV) and the corresponding total energy for each of the first 20 cases are shown in Table VII. In the followings are given explanations and comments to each individual case.

Case 1. *Configuration* A (*single configuration*)

Case 2. A+C (*semilocalization*)

Mixing of these two configurations is equivalent to HL type description with the use of "semilocalized" orbitals for valence electrons:

$$2s_a^{sl}=2\overset{\circ}{s}_a+\mu(2\overset{\circ}{s}_b) \text{ and } 2s_b^{sl}=2\overset{\circ}{s}_b+\mu(2\overset{\circ}{s}_a) \qquad (1)$$

Thus this improvement can be ascribed to the semilocalization of valence electrons. The total energy obtained is lower than that of Case 1 by 0.361 e.v., The value of μ in (1) is found to be negative, −0.0131.

Case 3. A+E (*s–p* hybridization)

Mixing of configuration E to configuration A means *s–p* hybridization. This gives the total energy lower than that of Case 1 by 0.325 e.v.

Case 4. $(g)^2$ *approximation*

In the single configuration approximation of Case 1 we adopted Schmidt-OMO's for molecular orbitals of valence electrons as well as core electrons, partly for the sake of mathematical simplicity. This result can be improved by using as orbitals for valence electrons a linear combination of Schmidt-OMO's σ_{2g} and σ_{3g}. The total energy thus obtained is lower than that of Case 1 by 0.275 e.v. The resulting normalized MO is here called g orbital, and the coefficients for expansions in terms of Schmidt-OMO's and of the unnormalized symmetry orbitals (I, (2) and I, (30)) are shown in Table VIII. We note here that this approximation is a counterpart of $(u)^2$ approximation in I (§ 4, Case 4).

Case 5. A+C+E *or* $g'g''$ *approximation*

The result of Case 1 can further be improved by using for two valence electrons two different MO's both of which are still linear combinations of Schmidt-OMO's σ_{2g} and σ_{3g}. Variational calculation has given the total energy lower than that of Case 1 by 0.386 e.v. or lower than that of Case 4 by 0.111 e.v. The resulting normalized MO's are here denoted by g' and g'', and the coefficients for expansions in terms of Schmidt-OMO's and of the unnormalized symmetry orbitals are shown in Table VIII.

Table VIII. Coefficients of Schmidt-OMO's[a] and unnormalized symmetry orbitals[b] in g, g', and g'' orbitals.

	Schmidt-OMO		Symmetry orbital		
	σ_{2g}	σ_{3g}	$(\sigma 1s)_g$	$(\sigma \overset{\circ}{2s})_g$	$(\sigma 2p)_g$
g	0.9844	0.1757	−0.0511	0.5174	0.1207
g'	0.8735	0.4868	−0.0674	0.3902	0.3343
g''	0.9808	−0.1952	−0.0263	0.5926	−0.1341

a) See Eq. (I, (3)).
b) See Eqs. (I, (2)) and (I, (30).

This approximation is a counterpart of $u'u''$ approximation in I (§ 4, Case 5) having a nature of the so-called (longitudinal) in-out effect.

Case 6. *The* LCAO SCF *method*

Roothaan's procedure[10] can be applied straightforwardly to our problem. SCF MO's (I, (23)) can be expressed in the form of linear combinations of Schmidt-OMO's as well as of those of the symmetry orbitals. These expansion coefficients of SCF MO's are given in Table IX.

For σ SCF MO's the orbital energies can be calculated directly by means of Roothaan's procedure. For π SCF MO's, however, it is not applicable, so that we use the following formulae

$$\varepsilon_a=h(a)+\sum_k\{2J(k,a)-K(k,a)\}$$ (2

($k=1\sigma_g$, $1\sigma_u$, and $2\sigma_g$; $a=1\pi_g{}^+$, $1\pi_g{}^-$, $1\pi_u{}^+$, or $1\pi_u{}^-$),

where $h(a)$ is one electron energy of φ_a orbital and $J(k, a)$ and $K(k, a)$ are Coulomb and Exchange integrals between φ_k and φ_a orbitals. The orbital energies thus calculated are also given in Table IX.

The total energy obtained is lower than that of Case 1 by 0.294 e.v. (Table VII). The wave function of Case 6 is superior to that of Case 4, because, in the former the form of the core orbitals is also improved. This improvement reduces the total energy by 0.019 e.v., which is fairly small.

Case 7. *σ-electron configurational interaction*

As long as two valence electrons are prescibed to occupy $2s_{a,b}$ and/or $2p\sigma_{a,b}$ AO's, the possible configurations are the first six, A to F in Table V. Taking into consideration these six configurations, we have performed the CI calculation. The total energy obtained is lower than that of Case 1 by 0.573 e.v.

Table IX. Coefficients of Schmidt-OMO's[a] and unnormalized symmetry orbitals[b] in SCF MO's,[c] and orbital energies.

$2\sigma_u$	−0.0106	0.9860	−0.1667		0.0113	0.7414	−0.2869		0.0290
$3\sigma_u$	−0.0057	0.1666	0.9860		0.3558	2.2311	−1.6972		0.3615
$1\pi_u{}^{\pm}$				1.0000				0.5939	0.0641

a) See Eq. (I, (3)). b) See Eq. (I, (2)). c) See Eq. (I, (23)).

Case 8. A+H (*transverse correlation*)

From Table V, it is found that besides A the contribution of configuration H is most important. Therefore, we have here considered only CI between A and H. The energy depression from the energy of Case 1 amounts to 0.473 e.v.

The wave function here obtained can be generated from the following primitive function:

$$\text{(normalization constant)}\times\{(\sigma_{2g}+\mu\pi_u{}^x)(\sigma_{2g}-\mu\pi_u{}^x)+(\sigma_{2g}+\mu\pi_u{}^y)(\sigma_{2g}-\mu\pi_u{}^y)\}\ \sigma_{1u}{}^2\ \sigma_{1g}{}^2, \tag{3}$$

where

$$\pi_u{}^x=\frac{1}{\sqrt{2}}(\pi_u{}^+ + \pi_u{}^-),$$

$$\pi_u{}^y=\frac{1}{\sqrt{2}\,i}(\pi_u{}^+ - \pi_u{}^-), \tag{4}$$

and

$$\mu=0.6605 \tag{5}$$

Thus, in this approximation, valence electrons are considered as occupying two orbitals, $\sigma_{2g}+\mu\pi_u{}^x$ and $\sigma_{2g}-\mu\pi_u{}^x$, or $\sigma_{2g}+\mu\pi_u{}^y$ and $\sigma_{2g}-\mu\pi_u{}^y$, and so the correlation between two valence electrons is to some extent taken into account, since these two orbitals are hybridized to opposite directions perpendicular to the molecular axis.

Case 9. A+C+H (*semilocalization and transverse correlation*)

In Case 2 some longitudinal correlation between two valence electrons has been taken into account by mixing configuration C, whereas in Case 8 some transverse correlation has been considered by mixing configuration H. Here both correlations are taken into consideration. Actually CI calculation has been performed with these three configurations, A, C, and H. The total energy obtained is lower than that of Case 1 by 0.696 e.v. From Table VII, it is found that the coefficient of H is large and is even larger than that of C. This fact can be understood as follows. In the ground state of the Be atom, it is expected that configurational mixing of $(1s)^2(2p)^2\sim(1s)^2\times\{(2p\sigma)^2+(2p\pi^x)^2+(2p\pi^y)^2\}$ to $(1s)^2(2s)^2$ is fairly important. Now $2p\sigma$, $2p\pi^x$, and $2p\pi^y$ orbitals in Be have a character resembling σ_{2u}, $\pi_u{}^x$, and $\pi_u{}^y$ orbitals of our Li_2 case, respectively, if, in the Li_2 ground state, charge distribution of valence electrons is approximately spherical. If the charge distribution were completely spherical, however, the amount of mixing of configuration $H\sim(\pi_u{}^x)^2+(\pi_u{}^y)^2$ would be twice as large as that of $C\sim\sigma_{2u}{}^2$.

Case 10. A+C+E+H (*semilocalization, hybridization, and transverse correlation*)

In Case 9 the effect of *s–p* hybiridization has not been considered, which also was found to be important from the result of Case 3. Configuration E is here added to those considered in Case 9. The energy depression from Case 1 is found to be 0.902 e.v.

Case 11. *Eight dimensional* CI

The results for this approximation were already given in Table V. The depression of the total energy from that of Case 1 is 0.941 e.v. By comparing these results with those of the previous case, we can see that four configurations considered in Case 10 are most important and the contribution of the remaining configurations is very small.

Case 12. *Pure* HL *approximation*

In the Heitler-London (HL) approximation, the structural wave function $\overset{\circ}{s}$-$\overset{\circ}{s}$ is adopted. This wave function is expressed in the form of a linear combination of A and C. The energy depression from Case 1 is 0.360 e.v., which shows that the HL approximation is, in our Li_2 case, better energetically than the MO approximation. This result is contrary to the situation found for the oxygen molecule (See I), and the reason for this difference will be discussed in paper III.

Case 13. *Ionic structure*

To see the feature of the ionic structure, we here employ the wave function of a simple ionic structure, $\overset{\circ\circ}{ss}-$. The total energy is higher than that of the pure HL approximation (Case 12) by 1.284 e.v.

From the results of Cases 2 and 12, it is found that

(i) the improvement of the pure HL approximation by semilocalization is fairly small, and that

(ii) the value of μ in Eq. (1) is small and negative, which shows the charge density between two nuclei, decreases slightly through semilocalization, contrary to the H_2 case.

Further the amount of ionic character can be seen by reexpressing the normalized wave function obtained in Case 2 as

$$\Phi\mathrm{so}=\frac{1}{d}\ \{(\overset{\circ}{s}-\overset{\circ}{s})+c(\overset{\circ\circ}{ss}-)\}\,, \tag{6}$$

where

$$d=0.9772, \text{ and } c=-0.0262.$$

Case 14. HL *with s–p hybridization*

Here the pure HL approximation (Case 12) has been improved by introducing *s–p* hybridization. The wave function for this purpose is constructed from the primitive function:

$$\Phi=(\text{normalization constant})$$
$$\times\{\phi_a\,\phi_b+\phi_b\,\phi_a\}\ (1s_a)^2\,(1s_b)^2\,,$$

with

$$\phi_a=2\overset{\circ}{s}_a+\lambda(2p\,\sigma_a)\,,$$
$$\phi_b=2\overset{\circ}{s}_b+\lambda(2p\,\sigma_b)\,. \tag{7}$$

Parameter λ has been determined by variational treatment and turned out to be 0.1558. Then the degree of *s–p* hybridization becomes 0.0237, if it is defined by $\lambda^2/(1+\lambda^2)$. The energy depression from the energy of the pure HL approximation (Case 12) is 0.120 e.v.

Case 15. HL *with semilocalization and s–p hybridization*

Both semilocalization and *s–p* hybridization can be taken into account by adopting the primitive function:

$$\Phi=(\text{normalization constant})$$
$$\times\{\phi_1\,\phi_2+\phi_2\,\phi_1\}(1s_a)^2\,(1s_b)^2\,, \tag{8}$$

where orbitals ϕ_1 and ϕ_2 have the form:

$$\phi_1\ \propto\ \{2\overset{\circ}{s}_a+\nu_1(2p\sigma_a)+\nu_2(2\overset{\circ}{s}_b)+\nu_3(2p\sigma_b)\}$$
$$\propto\ \{\sigma_{2g}+\kappa_1(\sigma_{3g})+\kappa_2(\sigma_{2u})+\kappa_3(\sigma_{3u})\}$$
$$+(\text{a linear combination of } \sigma_{1g} \text{ and } \sigma_{1u}),$$
$$\phi_2\ \propto\ \{2\overset{\circ}{s}_b+\nu_1(2p\sigma_b)+\nu_2(2\overset{\circ}{s}_a)+\nu_3(2p\sigma_a)\}$$
$$\propto\ \{\sigma_{2g}+\kappa_1(\sigma_{3g})-\kappa_2(\sigma_{2u})-\kappa_3(\sigma_{3u})\}$$
$$+(\text{a linear combination of } \sigma_{1g} \text{ and } \sigma_{1u}). \tag{9}$$

By variational calculation these parameters are found to be

$$\begin{aligned} \nu_1&=0.1597\,, & \kappa_1&=0.4625\,,\\ \nu_2&=0.0717\,, & \kappa_2&=0.1392\,,\\ \nu_3&=0.0066\,, & \kappa_3&=0.0511\,. \end{aligned} \tag{10}$$

The energy depression from the energy of the pure HL approximation (Case 12) is 0.141 e.v.

Case 16. $(\overset{\circ}{s}-\overset{\circ}{s})+(\pi-\pi)$ (HL *with transverse correlation*)

From the result of Case 8, the effect of perpendicular correlation in MO scheme turns out to be very remarkable. Here this effect has been reexamined with HL scheme by considering the resonance between two structures $(\overset{\circ}{s}-\overset{\circ}{s})$ and $(\pi-\pi)$. In this case, the wave function has the form:

$$\Phi=(\text{normalization constant})$$
$$\times\{(\overset{\circ}{s}-\overset{\circ}{s})+c(\pi-\pi)\}\,, \tag{11}$$

which can be constructed from the following primitive function:

$$\Phi=(\text{normalization constant})\times\{\Phi_{a,b}+\Phi_{b,a}\}\,,$$
$$\Phi_{a,b}=\{(2\overset{\circ}{s}_a+\tau\pi_a{}^x)(2\overset{\circ}{s}_b-\tau\pi_b{}^x)+(2\overset{\circ}{s}_a+\tau\pi_a{}^y)$$
$$\times(2\overset{\circ}{s}_b-\tau\pi_b{}^y)\}\times(1s_a)^2\,(1s_b)^2 \tag{12}$$

By variational calculation we have found that $c=--0.2262$ and $\tau=0.5836$, respectively. The energy depression from the energy of the pure HL approximation (Case 12) is 0.23[illegible] e.v.

Case 17. A′ (*assuming* S $(1s_a,\ 2\overset{\circ}{s}_b)=0$)

Here we have tried a calculation using the wave function obtained by replacing σ_{2g} in A′ by the normalized symmetry orbital $(\sigma 2\overset{\circ}{s})_g$ and assuming the overlap integral between 1*s* AO of one atom and $2\overset{\circ}{s}$ AO of the other atom to be zero. This approximation is similar to that adopted by Greenhow and Smith[11] and in Case 16 of I. The depression of energy from Case 1 is 0.603 e.v.

Case 18. HL′ (*assuming* S $(1s_a,\ 2\overset{\circ}{s}_b)=0$)

Here we have attempted a calculation similar to the preceding case (Case 17), by assuming S $(1s_a,\ 2\overset{\circ}{s}_b)=0$ in the calculation of Case 12. The depression of energy from Case 12 (pure HL) amounts to 1.329 e.v.

In the following cases, we shall examine the approximation of shrinking the (1*s*) core electrons into the nuclei (shrunk core model). The Hamiltonian is written as

$$H=-\tfrac{1}{2}\sum_{i=1}^{2}\Delta_i-\sum_{i=1}^{2}\left(\frac{1}{r_{ai}}+\frac{1}{r_{bi}}\right)$$
$$+\frac{1}{r_{12}}+\frac{1}{R}\,, \tag{13}$$

and the electron configurations can be obtained by omitting the orbitals of the core electrons in configurations A, B, ... of Table IV, and they will be designated by the same notation A, B, ... for the sake of convenience.

Case 19. A (*shrunk core*)

We have here employed the configuration in which the two valence electrons occupy Schmidt-OMO σ_{2g}, namely configuration A.

Case 20. Eight dimensional configurational interaction (*shrunk core*)

On the assumption of shunk core model, eight dimensional CI calculation similar to Case 11 is here performed. The depression of the total energy from the preceding case is 1.439 e.v. In this case, the mixing of configuration H is much more pronounced than in the case of the complete treatment (Case 11). This may be understood as follows. In the shrunk core model, the incompleteness of the screening effect due to (1*s*) electrons is perfectly neglected. Therefore the energy of (2*s*) orbital, of which the penetration into (1*s*) core is appreciable, is overestimated. Thus the energy difference between A and H has a smaller value than in the case of the complete treatment (Case 11).

Case 21. $\mathring{s}$–$\mathring{s}$ (*pure* HL *on shrunk core model*)

Here we have taken the wave function to be obtained by shrinking the core electrons in Case 12 (pure HL). The total energy is found to be −0.33526 a.u. and to be lower than that of the preceding case by 1.122 e.v. This is not surprizing since orbital (2$\mathring{s}$) is not orthogonal to the core orbital of the neighbouring atom, contrary to Schmidt-OMO σ_{2g}.

Case 22. *s*–*s* (*Rosen-Ikehara's treatment*)

Here we have used the nodeless Slater AO, 2*s*, in place of 2$\mathring{s}$ in the wave function of the preceding case. This approximation is nothing but that adopted already by Rosen-Ikehara[3]. The total energy is found to be −0.53743 a.u.

§ 4. Calculation of Energy of Excited States

In this section, we investigate the three lower excited states, $^1\Sigma_u^+$, $^3\Sigma_u^+$, and $^1\Pi_u$ explained in § 2. All the configurations within our framework for each of these states are listed in Tables X and XI.

Table X. Configurations[a] used in CI calculation for $^3\Sigma_u^+$ and $^1\Sigma_u^+$ states.

i	σ_{1g}	σ_{2g}	σ_{3g}	π_g^+	π_g^-	σ_{1u}	σ_{2u}	σ_{3u}	π_u^+	π_u^-
A	2	1				2	1			
B	2	1				2		1		
C	2		1			2	1			
D	2		1			2		1		
E	2			1		2				1

a) See the footnote a) of (I, Table IV).

Table XI. Configurations[a] used in CI calculation for $^1\Pi_u$ state.

i	σ_{1g}	σ_{2g}	σ_{3g}	π_g^+	π_g^-	σ_{1u}	σ_{2u}	σ_{3u}	π_u^+	π_u^-
A	2	1				2			1	
B	2		1			2			1	
C	2			1		2	1			
D	2			1		2		1		

a) See the footnote a) of (I, Table IV).

For each set of parameters (α, β) and each value of R stated in § 2, the total energies E_0 for configuration A are calculated. Further, the improved calculation is carried out by taking all the configurations into account. The energies, and the coefficients of configurations in the resulting wave function are listed in Tables XII, XIII, and XIV.

b) The energy of the configuration $(\sigma_{3g}\pi_u{}^+)$ is −0.1994 a.u., which is lower than −0.1948 a.u. of A.

Next, we shall apply some of the approximations, considred in § 3, to the excited states for $R=5.0$ a.u. using parameter Set II.

a) *Pure* HL *approximation*

The HL wave functions, Φ_{HL}, are constructed from the following primitive functions:

$$(\text{normalization constant})\times(2\mathring{s}_a\,2\mathring{s}_b-2\mathring{s}_b\,2\mathring{s}_a)\,(1s_a)^2\,(1s_b)^2 \text{ for } {}^3\Sigma_u{}^+,$$

$$(\text{normalization constant})\times(2\mathring{s}_a\,2\mathring{s}_a-2\mathring{s}_b\,2\mathring{s}_b)\,(1s_a)^2\,(1s_b)^2 \text{ for } {}^1\Sigma_u{}^+,$$

and

$$(\text{normalization constant})\times(2\mathring{s}_a\,\pi_b{}^+-2\mathring{s}_b\,\pi_a{}^+)\,(1s_a)^2\,(1s_b)^2 \text{ for } {}^1\Pi_u\,. \quad (14)$$

By using the configurations of Tables X and XI, Φ_{HL} are expressed as

$$\Phi_{\mathrm{HL}}({}^3\Sigma_u{}^+)=\mathrm{A}\,,\qquad \Phi_{\mathrm{HL}}({}^1\Sigma_u{}^+)=\mathrm{A}\,,$$
$$\Phi_{\mathrm{HL}}({}^1\Pi_u)=0.9504\ \mathrm{A}-0.3109\ \mathrm{C}\,. \quad (15)$$

Namely, for both $^3\Sigma_u{}^+$ and $^1\Sigma_u{}^+$ states, the pure HL approach coincides with the single configuration A. For $^1\Pi_u$ state, the total energy obtained is −14.7392 a.u., and so the depression of energy from that calculated by

) A (*shunk core*)

A calculation similar to Case 19 of the round state is made by omitting the core rbitals in each configuration A of the excited states. The obtained total energies E_0 are given in Table XV.

We notice here that, in this shrunk core model, A is the lowest configuration for $^1\Sigma_g{}^+$, $^3\Sigma_u{}^+$, and $^1\Sigma_u{}^+$ states, whereas for $^1\Pi_u$ state B is the lowest one.

c) *Full configurational interaction* (*shrunk core*)

Here we have investigated, for each state, the treatment similar to Case 20 of § 3, where all the configurations derived from configuration A, B,... by dropping the core orbitals are taken into account. For convenience the latter configurations are also denoted by the same notation A, B,... The coefficients of configurations in the wave function here obtained and the energies are listed in Table XV.

The vertical excitation energies from the ground state to each of the excited states are obtained by taking the differences of the respective total energies calculated for each set of parameters and each R, (i) by the single configuration A, (ii) by considering all the configurations in Tables IV, X, and XI. The results are given in Table XVI, together with the observed ones obtained by using Morse potentials:

$$U(R) = T_e + D_e[1 - \exp\{-\beta(R - R_e)\}]^2 . \quad (16)$$

In this formula, the values of parameters T_e, D_e, R_e, and β are determined by using the spectroscopic data[12)] and are given in Table XVII. Further, the vertical excitation energies are calculated by using the results of approximations (a), (b), and (c) for Set II and R=5.0 and are shown in Table XVIII. All the results obtained for Set II and R=5.0 are also compared with the observed ones in Fig.

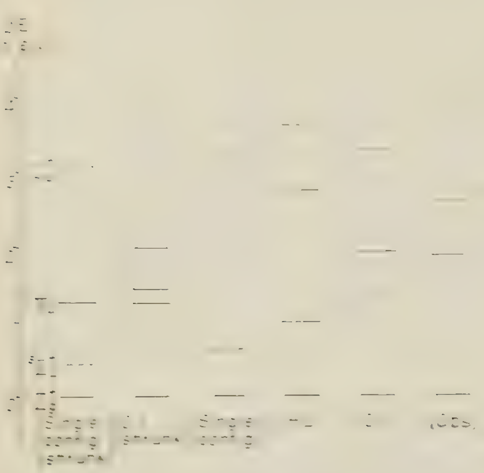

Fig. 1. Comparison of energy levels calculated by various approximations with experiment.

From Tables XVI, XVIII and Fig. 1, w can see that the order of the levels for ${}^1\Sigma_u$ and ${}^1\Pi_u$ states changes by introducing CI t agree with the experiment. Further the valu of the vertical excitation energy for ${}^1\Sigma_u^+$ fairly improved due to CI, though for ${}^1\Pi$ state CI makes the result a little worse. Th defect may be removed by using a better orbital.

Moreover, from Table XVIII and Fig. 1 w can see that, in case the inner shells a neglected, the results are improved for bot ${}^1\Sigma_u^+$ and ${}^1\Pi_u$ states by taking CI into accoun although the coefficients of the configuratio are very different from those obtained by in cluding the inner shells.

§ 5. Molecular Quantities

By using the wave functions obtained in § and § 4. (1) the depth of adiabatic potenti

a) See Eq. (17)

$D(R)$ for each state, (2) the molecular quadrupole moment Q, (3) the oscillator strength f_{lk}, and (4) the gradient of the electric field at the nucleus q, are calculated. These values serve for discussing the features of the various approximations employed in this paper, though, unfortunately the observed values are not available for them except $D(R)$.

(*1*) *Adiabatic potential* $U(R)$

The depth of adiabatic potential $D(R)$ is given by

$$D(R)=E(R_\infty)-E(R)\,, \tag{17}$$

where $E(R)$ and $E(R_\infty)$ are the energies of the molecule in the state under consideration at a finite internuclear distance R and at the infinite nuclear separation R_∞, respectively.

In our case, it is easily shown that

$$E(R_\infty)=E(^2S)+E(^2S) \text{ for } {}^1\Sigma_g{}^+ \text{ and } {}^3\Sigma_u{}^+$$

and

$$E(R_\infty)=E(^2S)+E(^2P) \text{ for } {}^1\Sigma_u{}^+ \text{ and } {}^1\Pi_u\,, \tag{18}$$

where $E(^2S)$ and $E(^2P)$ are the energies of the free Li atom in the ^2S and ^2P states, respectively. These $E(^2S)$ and $E(^2P)$ are calculated by using the wave functions constructed from primitive functions $(1s)^2$ $(2\mathring{s})$ and $(1s)^2$ $(2p)$, respectively, both of which are built from Slater AO's (I, (1)) with the orbital exponents δ_1 and δ_2 shown in Table II. The results of the calculation are given in Table XIX. From this table we can see the values of $E(R_\infty)$ easily. By subtracting the value of $E(R)$ from that of $E(R_\infty)$ for each fixed parameters δ_1, δ_2, and R, we have obtained $D(R)$ associated with the two kinds of approximations (single configuration and CI) for each state. The results are given in Table XX. The observed values of $D(R)$ have been derived by using the Morse potentials constructed in § 4, and these are given in the same table.

From this table, we can see that (i) the effect of CI is very important, (ii) the results

Obs.	1.05					

a) See Eq. (21).
b) See Eq. (22).
c) James' calculation was made at $R=5.63$ a.u. and so the q' value in this table is also the one at $R=5.63$ a.u.[13)]

of CI calculation are fairly good for ${}^1\Sigma_g{}^+$ and ${}^1\Sigma_u{}^+$, but not so for ${}^1\Pi_u$, and (iii) the observed value of $D(R)$ is larger than the calculated ones except the one case, that is for ${}^1\Sigma_u{}^+$ state, $R=4.5$, and Set III.

Now, since for $R=5.0$ and Set II $E(R)$ was calculated by using various approximations in §§3 and 4, we can obtain the corresponding $D(R)$'s easily. As the values $E({}^2\mathrm{S})$ and $E({}^2\mathrm{P})$, we have adopted the same ones as were used in calculating $D(R=5.0)$ for Set II in Table XX, except the cases of shrinking the inner shells. In the latter cases we use, as those, the energy of a system composed of one electron and a proton, which is calculated by using the same Slater AO, $2\overset{\circ}{s}$, $2s$, or $2p$ as was used in calculating the respective $E(R)$. These values are

$$\begin{aligned} E({}^2\mathrm{S}) &= -0.13311\,64 \text{ a.u. for } 2\overset{\circ}{s}\,, \\ &= -0.25458\,33 \text{ a.u. for } 2s\,, \\ E({}^2\mathrm{P}) &= -0.11375\,00 \text{ a.u.}\,. \end{aligned} \tag{19}$$

The values of $D(R=5.0)$ thus obtained are given in Table XXI for the excited states. Those for the gound state are given in Table XXII as the dissociation energy D_e, since the observed equilibrium internuclear distance differs little from 5.0 a.u. In Fig. 2, all the results of D_e obtained for Set II are compared with the experiment.

Table XXI shows that the result is disappointing for ${}^1\Pi_u$ state. In addition, in the approximation of shrunk core model in MO scheme, even if CI is taken into account, the result is poor also for $^1\Sigma_u{}^+$ state.

Next, from Table XXII and Fig. 2, we can see the following points:

(a) The dissociation energy D_e given by our best approximation (Case 11) amounts to 0.77 e.v., which is about 73% of the observed one. This value is a little better than the result of the most elaborate calculation hitherto performed by James[4)] and Harris-Melkanoff[13)] (0.51 e.v.), though the latter authors employed, as the energy of the Li atom $E(^2S)$, the one obtained by using Wilson's four parameter function[14)], which is lower than ours by 0.072 e.v.

(b) D_e by the pure HL approximation (Case 12) is 0.19 e.v. James [4)] also made a similar calculation to ours assuming $\delta_1=2.68$, $\delta_2=0.670$, and $R=3.18$ Å, and obtained $D_e=0.265$ e.v. The reason of the discrepancy of our result from James' one lies in the different choice of the parameters δ_1, δ_2, and R.

(c) D_e obtained by assuming $S(1s_a, 2\overset{\circ}{s}_b)=0$ in the single configuration A (Case 17) is rather good, whereas the one obtained by the same assumption in the pure HL approximation (Case 18) turns out to be much larger than the observed value.

(d) In the shrunk core model in MO type, the result of the single configuration A (Case 19) is not so good, but this is improved appreciably by introducing CI (Case 20). The result obtained in the latter case almost coincides with our best result (Case 11).

(e) In a shrunk core model of HL type, D_e given by the structure ($\overset{\circ}{s}$-$\overset{\circ}{s}$) (Case 21) is found to be 1.878 e.v., which shows that this simplified approximation can not be safely applied to obtain a reasonable value of D_e.

(f) If we use nodeless Slater AO's $2s$ (Case 22) in place of $2\overset{\circ}{s}$ in the above approximation, however, we can obtain $D_e=0.769$ e.v., which is almost as good as our best calculated value (Case 11). Rosen and Ikehara[3)] already performed the similar calculation assuming somewhat diffferent values for parameters, namely, $\delta_2=0.65$ and $R=2.28$,Å and obtained D_e of 1.11 e.v. Since the reason of their good result was criticized in detail by James [4)], we do not discuss further on this point.

Finally, we remark the fact that, as to the result of CI calculation based on the shrunk core model for $^1\Sigma_u{}^+$ and $^1\Pi_u$ states, the agreement of the calculated to observed value is disappointing for $D(R)$ but it is not so wrong for $\Delta E(R)$. (See Tables XVIII and XXI.) This situation suggests that the calculated value of $\Delta E(R_\infty)$ is inaccurate, because

$$D_{\text{excited}}(R)-D_{\text{normal}}(R)=\Delta E(R_\infty)-\Delta E(R). \quad (20)$$

For the sake of comparison, we give in Table XXIII $E(^2P)-E(^2S)$ values calculated by each approximation using Slater orbitals of Set II and $R=5.0$ a.u. The fact that the value of $E(^2P)-E(^2S)$ obtained by using nodeless Slater AO ($2s$) in a shrunk core model is very large compared with the experiment[15)] was already pointed out by Rahman [16)].

(2) *Molecular Quadrupole Moment Q*

The molecular quadrupole moment Q is given by

$$Q=\int r^2(3\cos^2\theta\ -1)\,\rho\,dv=ZR_2$$
$$-2\langle z^2\rangle+\langle x^2+y^2\rangle, \quad (21)$$

where Z is the nuclear charge and is equal to 1 or 3 according as the inner core electrons are shrunk or not. ρ is the charge density of the nuclei and electrons. The meanings of θ, $\langle z^2\rangle$, and $\langle x^2+y^2\rangle$ are the same as

Table XXIII. Values of $E(^2P)-E(^2S)$[a)] (in a.u.) obtained by using Slater orbitals of Set II and $R=5.0$ a.u.

a) See Eqs. (18) and (20).

those of I, § 6. We have calculated $<x^2+y^2>/R^2$, $<z^2>/R^2$, and Q, using the single configuration and CI wave function for each parameters α, β, and R. The result is given in Table XXIV. From this table we can see the following facts.

(a) For a fixed R, Q increases as the orbital exponent δ_2 decreases. This can be understood by considering that the charge density of the valence electrons in the neighbourhood of the molecular axis decreases as δ_2 decreases.

(b) For a fixed set, the value of Q calculated by the single configuration increases in proportion to R^2. This increasing tendency of Q with R is seen even in CI calculation though its dependency on R^2 no longer holds, and is too large to be ascribed to the fact mentioned in (a). Thus, we can expect that the calculated Q value increases with R in the neighbourhood of the equilibrium internuclear distance, even if the same values of the orbital exponents δ_1 and δ_2 are used.

We note here that Q for $R=0$ is negative, since, in this limiting case, the ground state of Li_2 becomes ^1D state of a carbon atom and the corresponding Q is -2.2722 a.u. if calculated by using Slater AO's with the orbital exponent $\delta_2=1.625$, whereas Q for the infinite nuclear distance is of course zero. Considering that the calculated values of Q are positive in the neighbourhood of the equilibrium internuclear distance, we can expect that the value of Q increases from a negative value at $R=0$ to a positive one and tends to zero at the infinite nuclear separation.

Further, in Table XXII, $<z^2>/R^2$, $<x^2+y^2>/R^2$, and Q calculated by using the various wave functions for Set II and $R=5.0$ a.u. obtained in § 3 are given. From this table we can see the following situation.

(a) The calculated values of Q can be classified, as a whole, into two groups, namely, the one around 20 a.u. and the other smaller than 10 a.u., depending on whether s–p hybridization is taken into account or not. This difference comes mainly from that of $\langle z^2\rangle$. The fact that $\langle z^2\rangle$ decreases by introducing s–p hybridization is reasonable, since we can expect that the charge density in the region between two nuclei increases by s–p hybridization. In the O_2 molecule, we encountered a similar situation, though the effect of s–p hybridization on the charge density in that case is of the opposite direction.

(b) Values of Q of Case 2 (semilocalization) and Case 12 (pure HL approximation) are smaller than that of Case 1 (single configuration) mainly due to the fact that the values of $\langle z^2\rangle$ of the former cases are larger than that of the latter. This result is reasonable since the charge density of σ_{2u} orbital is larger than that of σ_{2g} in the outer region of the molecule.

(c) The Q value of Case 2 is even smaller than that obtained byt he pure HL approximation (Case 12). This fact can be expected since μ in Eq. (1) is negative. (See the discussion in the end of Case 13, § 3.)

(d) The effect of mixing the configurations involving π orbitals increases the value of $\langle x^2+y^2\rangle$ and accordingly increases that of Q. (Compare Cases 1 and 8, and Cases 12 and 16.)

(e) Q obtained by the pure ionic structure (Case 13) coincides with that obtained by the pure HL approximation (Case 12), since the charge density is identical for these two approximations.

(f) Contrary to the case of D_e, Q value does not change appreciably by assuming $S\,(1s_a, 2s_b)=0$. (Compare the Q values of Cases 1 and 17. and Cases 12 and 18.)

(g) Q values obtained by the various approximations in the shrunk core model are not so different from those obtained by the corresponding ones including the inner shells. (Compare Q values of Cases 1 and 19, Cases 12, 21, and 22, and also Cases 11 and 20.)

Now we have undertaken to see the variation of Q due to the use of different approximations for the valence electrons. For this purpose, we have defined $\langle Q\rangle_{val}$, which is considered to be the contribution of the charge density of valence electrons by the following equation:

$$Q=R^2-\langle Q\rangle_{val}\,, \tag{22}$$

that is

$$\langle Q\rangle_{val}=\{2\langle z^2\rangle-\langle x^2+y^2\rangle\}-2R^2\,, \tag{23}$$

since, in the approximations considered in this paper except SCF, Q can be expressed as

$$Q=3R^2-\langle Q\rangle_{val}-\langle Q\rangle_{core}\,,$$

where $-\langle Q\rangle_{core}$ is the contribution of the core electrons to Q, and is closely equal to $-2R^2$. The numerical values of $\langle Q\rangle_{val}$ are shown in (C) of Table XXIV. Since, in the actual electron distribution, $\langle Q\rangle_{val}$ is expected to be negative, the upper limit of Q will be R^2. The results given in Tables XXII and XXIV are contradictory to this fact. The fact that the value of $\langle Q\rangle_{val}$ in CI calculation is very small means that the charge distribution of the valence electrons is nearly spherical around the center of the molecule.

(3) *Gradient of Electric Field at a Nucleus, q.*

The gradient of the electric field at one nucleus, q, is defined by

$$\left.\begin{aligned} q&=2eq' \\ q'&=\int\frac{3\cos^2\theta_a-1}{2r_a{}^3}\,\rho dv \\ &=\frac{Z}{R^3}-\langle q_a'\rangle, \\ \langle q_a'\rangle&=\int\frac{3\cos^2\theta_a-1}{2r_a{}^3}\,\rho_{el}dv\,, \end{aligned}\right\} \tag{24}$$

where ρ_{el} is the number density of electrons, and the meanings of r_a, and θ_a are explained in § 6, (2) and (3) of I. Since q' is zero in the ground state of a Li atom, it becomes zero at the infinite internuclear distance for the Li_2 ground state. Even in the neighbourhood of the equilibrium internuclear distance, q' is expected to be close to zero, and so it is difficult to assess the accurate value for q'.

In order to study the dependence of $\langle q_a'\rangle$ and q' on R and the parameter value δ_2, we have calculated the values of these quantities for three values of R with the use of the single configurational wave function (A) as well as CI wave function, for three different sets of (α, β). From Table XXIV, in which our results are given, we note that Z/R^3 and $-\langle q_a'\rangle$ almost cancel with each other, yielding very small values for q'. This makes the reliable estimate of q' very difficult: we note, however, that all values obtained in this way are positive. Further from this table we can see the following facts.

(a) For a fixed value of R, q' increases (or $\langle q_a'\rangle$ decreases) with decreasing δ_2. This is reasonable since the charge distribution of the valence electrons in the neighbourhood of the molecular axis decreases with decreasing δ_2, whereas that near the nucleus A is roughly spherically symmetric around that nucleus, irrespectively of δ_2.

(b) For a fixed set, q' decreases with increasing R (or decreasing δ_2). This can be easily seen as follows: $R^3 <q_a'>$, which is independent of R on the single configurational wave function, is found to be a increasing function of R when CI wave function is employed. Hence $R^3\ q'$ which is equal to $Z-R^3 \times <q_a'>$, is a decreasing function of R, and q' decreases with R more rapidly than R^{-3}, provided that q' is positive.

From (a) and (b) we can conclude that, for a constant δ_2, q' decreases with increasing R, at least in the neighbourhood of the equilibrium internuclear distance R_e.

As to the dependence of q' on R over the whole range $(0, \infty)$, the following discussions might be of some interest. In the limit of the united atom, that is, in ^{1}D of the carbon atom, the value of $<q_a'>$ calculated by using Slater AO with $\delta_2=1.625$ is 0.57124 a.u., which in the limit of the infinite nuclear separation is of course zero. Further, for any finite value of R, $<q_a'>$ is expected to have a positive value. Accordingly, q' is infinitely large at $R=0$ and becomes zero at $R=\infty$ and its upper limit is $3/R^3$ for any R. The situation mentioned in (b) suggests that in the neighbourhood of the equilibrium internuclear separation, q' is positive and a decreasing function of R. It may be quite possible, however, that q' becomes negative at a certain value of R larger than the equilibrium internuclear distance R_e.

Further, the values of q' calculated by using the various approximations for Set II and $R=5.0$ a.u. obtained in § 3 are given in Table XXII. From this table, we can see the following points.

(a) Similarly to the case of Q, the calculated q values can be divided into two groups. Namely, if s–p hybridization is not considered q' is larger than 30×10^{-4} a.u., whereas it is smaller than 16×10^{-4} a.u. if s–p hybridization is taken into account. This variation of q' is reasonable, since s–p hybridization increases the charge density in the neighbourhood of the molecular axis.

(b) Contrary to the case of Q, the effect of semilocalization is not so important. (Compare Case 1 with Cases 2 and 12.)

(c) By mixing the configurations which involve π orbitals, q' value becomes fairly large (Compare Cases 1 and 8, Cases 12 and 16.)

(d) The pure ionic structure (Case 13) an the pure HL approximation yield the same q value, similarly to the case of Q.

(e) No appreciable difference is found betwee Cases 1 and 17, and Cases 12 and 18. Tha is, contrary to the Q value of O_2, the assumption of $S(1s_a, 2\mathring{s}_b)=0$ does not appreciably affect the q' value of Li_2.

(f) The q' values for the various approximations in the shrunk core model are close t those for the corresponding approximation involving the inner shells. (Compare Cases and 19, and Cases 12, 21, and 22.) The onl one exception exists between Cases 11 an 20. This is easily understood, however, b considering that the amounts of mixing o each configuration are quite different for thes two cases.

Now to investigate the contribution to q' o only the valence electrons, we have define $<q_a'>_{val}$ by the relations similar to Eqs. (22 and (23) mutatis mutandis, namely.

$$q'=\frac{1}{R^3}-<q_a'>_{val}\ , \qquad (25$$

or

$$<q_a'>_{val}=<q_a'>-\frac{2}{R^3}\ , \qquad (26$$

The values of $<q_a'>_{val}$ obtained by usin the single configuration and CI wave functio for each parameter set and R are given i (C) of Table XXIV. From this table we ca see that, as Harris and Melkanoff predicted[13] $<q_a'>_{val}$ is not very sensitive to the chang of R.

Accordingly, assuming $<q_a'>_{val}$ to be constant with respect to R, we have estimate q', for the equilibrium internnclear distanc $R_e=5.05$ a.u. using Eq. (25). The results fo the single configuration, pure HL approximation, and eight dimengional CI considered i § 3 for Set II and $R=5.0$ a.u., together wit the ones obtained by Harris-Melkanoff an also Sternheimer[17] by using the pure HL wav function and the James variational wave function, are shown in Table XXV.

The difference of their result obtained b using the James variational function from our mainly comes from the following features of the James wave function.

(a) Charge density of valence electrons increases in the neighbourhood of the molecular axis by mixing more basic functions of σ type than ours.

(b) In his function, transverse correlation of π type which will decrease the charge density near the molecular axis is not considered. Further, their assumption is somewhat doubtful, that $\langle q_a'\rangle_{val}$ is almost constant over the wide region of R around R_e.

Now, we note that, in order to obtain the value of q' in fair accuracy, we may have to consider the effect of departure from spherical symmetry of the core electrons, that is, Sternheimer correction17). The results of this correction calculated by Sternheimer and Foley17), using the pure HL and the James variational function, are given in Table XXV. Then, assuming that the corrections for our single configuration and pure HL is equal to his correction for his pure HL, and that the correction for our CI wave function are equal to his for the James variational wave function, we have made a rough estimate of this correction and the result is added in Table XXV with parentheses. From this table we can expect that q' still remains positive though it is reduced appreciably by this correction.

Finally we have averaged the value of q' over the zero point vibration by assuming $\langle q_a'\rangle_{val}$ to be constant with respect to R. Then the averaged value $\langle q_a'\rangle_{00}$ is

$$\langle q'\rangle_{00}=\langle \frac{1}{R^3}\rangle_{00}-\langle q'_a\rangle_{val}\,,$$

where $\langle 1/R^3\rangle_{00}$ is the average of $1/R^3$ over the zero point vibration. Inserting $\langle 1/R^3\rangle_{00}$ calculated by using Morse potential (Table XVII) and the formulae given by E. Ishiguro and others18), we have

$$\langle q'\rangle_{00}=\frac{1}{R_e^3}-\langle q_a'\rangle_{val}-0.00007(\text{in a.u.})\,.$$

Thus the departure of $\langle q'\rangle_{00}$ from $q'(R_e)$ is very small.

By using the value of $\langle q'\rangle_{00}$ obtained by our best wave function, and by neglecting or including Sternheimer correction, the nuclear quadrupole moment of Li^7, $Q(\mathrm{Li}^7)$, is estimated as $+9.6\times10^{-26}\,\mathrm{cm}^2$ or $+10.8\times10^{-26}\,\mathrm{cm}^2$, respectively, from the observed value of eqQ (Li): +0.060 MC/sec19). This positive signe of Q(Li) is contrary to the result obtained by using the James function and also to the prediction from the side of a simple application of the nuclear shell model. This prediction, however, does not seem to be so conclusive, because configurational interaction, inclusion of tensor force etc. may alter the situation.20)

(*4*) *Oscillator Strengths f_{lk}*

As explained in I, §6, subsection (4), the oscillator strength f_{lk} for transition from a state l to another state k ($E_k>E_l$) can be calculated by either the dipole length or the dipole velocity method, that is

$$f_{lk}=\frac{2}{3}\;|(\sum_i \boldsymbol{r}_i)_{lk}|^2\;(\Delta E)_{lk} \qquad (27)$$

or

$$f_{lk}=\frac{2}{3}\,|(\sum_i \nabla_i)_{lk}|^2/(\Delta E)_{lk}\,, \tag{28}$$

respectively.

Now among the four states considered in this paper, it is easily seen that the possible transitions are only ${}^1\Sigma_g^+-{}^1\Sigma_u^+$ and ${}^1\Sigma_g^+-{}^1\Pi_u$. The former corresponds to the one electron jump $\sigma_{2g}-\sigma_{2u}$ and is induced by z components of the dipole length and velocity. The latter corresponds to the one electron jump $\sigma_{2u}-\pi_u^{\pm}$ and is induced by x and y components of them.

The matrix elements of the dipole length and velocity corresponding to these two transitions are calculated by using the same wave functions as were used in calculating $(\Delta E)_{lk}$ of Table XVI and the result is shown in Table XXVI. By using these values of matrix elements together with the respective $(\Delta E)_{lk}$'s given in Table XVI, f_{lk}'s are calculated and the result is given in Table XXVII.

From this table we can see that

(a) when CI is taken into account, the results obtained by these two methods agree fairly well for each set and R, and further the difference of f_{lk}'s due to the different choice of parameter sets and R is reduced appreciably,

(b) in general, the f_{lk} value obtained by the length method is larger than that by the velocity method, except the one, namely f_{lk} for ${}^1\Sigma_g^+-{}^1\Pi_u$ obtained by using Set III and $R=4.5$ a.u., and that

(c) contrary to the case of ${}^3\Sigma_g^- - {}^3\Sigma_u^-$ transition in the O_2 case, f_{lk} calculated by the velocity method increases by introducing CI.

Further we have carried out a calculation using the various wave functions obtained for Set II and $R=5.0$ a.u. The necessary matrix elements of the coordinate and velocity are shown in Table XXVIII, while $(\Delta E)_{lk}$ can be taken from Table XVIII. The resulting values of f_{lk} are listed in Table XXIX.

From this table, we can see that, similarly to the case of D_e, the results of the pure HL approximation are somewhat better than those of the single configuration.

Further, as to the transition probability for ${}^1\Sigma_g^+-{}^1\Pi_u$, the results obtained by the shrunk core model are very different from those by including the inner shells. This fact is one

CI (shrunk core)	1.49	6.67
Obs.	1.86	2.59

of the most conspicuous shortcoming of the shrunk core model.

Finally, the values of $(\Delta E)_{lk}$ are calculated by the following formula:

$$\langle \Delta E\rangle_{lk} = \frac{\langle \sum_i \partial/\partial u_i \rangle_{lk}}{\langle \sum_i u_i \rangle_{lk}}, \quad v=x, y, \text{ or } z\,. \tag{29}$$

Here we have used the values of the matri elements of the dipole length and the corresponding ones of the dipole velocity shown in Tables XXVI and XXVIII. The results are given in Table XXX.

As can be seen from this table, the very good agreement with the observation is obtained by taking CI into account. The only one exception exists, namely $<\Delta E>_{lk}$ of ${}^1\Sigma_g^+ - {}^1\Pi_u$ obtained for Set III and $R=4.5$ a.u. Further, we can see that the situation similar to the case of the f_{lk} values holds also for the $<\Delta E>_{lk}$ values obtained by using the HL approximation and the shrunk core model. (See (B) of this table.)

§ 6. Population Analysis

As introduced in Part I, various specific overlap and specific AO populations in orthonormalized MO

$$\varphi=\sum_i c_{i,\,rk}\,\chi_{rk}\ (r=a,b;\ k=1s,\,2\overset{\circ}{s},\,2p\sigma,\,2p\pi^{\pm}) \tag{30}$$

have the following forms:

$$n'(i;\,k,\,l)=\begin{cases} 2c_{i,\,ak}\,c_{l,\,bk}\,S_{ak,\,bk} & \text{for } k=l \\ 4c_{i,\,ak}\,c_{i,\,bl}\,S_{ak,\,bl} & \text{for } k\neq l\,, \end{cases} \tag{31.1}$$

$$n'(i)=\sum_{k\geqq l} n'(i;\ k,\ l)\,, \tag{31.2}$$

$$N'(i;\,k)=c_{i,\,ak}^2+c_{i,\,bk}^2+2\sum_l c_{i,\,ak}\,c_{i,\,bl}\,S_{ak,\,bl}\,, \tag{31.3}$$

where $S_{rk,\,sl}=\int \chi_{rk}\,\chi_{sl}\,dv$. Then the overlap population $n(i)$, gross AO population $N(i;\,k)$, and total overlap population n. defined by Mulliken[21] can be expressed as

Table XXXI. Coefficients $c_{i,rk}$[a)] in MO φ_i.

Table XXXVI. Total overlap populations $n^{a)}$ and $s-p$ promotion in percent.

Method	Single configuration	g^2	SCF	8 dim. CI
n	0.7269	0.8606	0.8456	0.6825
$s-p$	0	9.49	9.36	13.82

a) See Eq. (32.3).

overlap populations $n(i)$ and n can be taken as a measure of "bonding power".

To investigate the features of the three wave functions, (A) the single configuration (Case 1), (B) g^2 (Case 4), and (C) SCF MO (Case 6), obtained for the ground state and for Set II and $R=5.0$. a.u., we have calculated the various populations by the above formulae. The coefficients in Eq. (30) for the wave functions (B) and (C) were already given in Tables VIII and IX, respectively. Those for (A) are given in Table XXXI. The obtained results of the various populations are summarized in Tables XXXII, XXXIII, and XXXIV.

Further, as explained in I, we can also analyze the eight dimensional configurational wave function (Case 11) using the above formulae, if MO φ_i and the occupation number $N(i)$ in the above formulae are replaced by the natural orbital[22)] φ_i' and the effective number of electrons N(i). (See Eq. (I, (60).) The coefficients $c_{i,\ rk}$ in the natural orbital φ_i' are given in Table XXXI. The obtained results of the various populations are given in Table XXXV.

Table XXXVII. Comparison between values of $(n_0-n_k)/n_0{}^{a)}$ calculated by (SCF)′ rnd CI, together with experimental values of $2(R_k-R_0)/R_0{}^{a)}$.

k	$(n_0-n_k)/n_0$	$2(R_k-R_0)/R_0$	Remarks
$Li_2(^1\Pi_u)$	0.1585 (0.5045)[b)]	0.1975	One electron in $Li_2(^1\Sigma_g{}^+)$ being excited from $2\sigma_g$ to $1\pi_u{}^\pm$
$Li_2(^1\Sigma_u{}^+)$	0.8192 (0.5648)[b)]	0.3257	One electron in $Li_2(^1\Sigma_g{}^+)$ being excited from $2\sigma_g$ to $2\sigma_u$

a) See Eq. (33).

b) The values within parentheses are those calculated by using CI wave functions.

Table XXXVIII. Values of kinetic energy T in a.u. for wave function for each set and each R.

The amounts of s–p promotion and the total overlap population n, obtained by the population analysis method for the above four wave functions, are given in Table XXXVI. From this table we can see the following points.

(a) The charge distribution is nearly the same for SCF and g^2 wave functions.

(b) The values of n for SCF and g^2 wave functions are larger than that for the single configurational wave function. This tendency is, however, not so remarkable as that encountered in the case of O_2, though the amount of s–p promotion is comparable. (cf. Table XIX of Part I.)

(c) The value of n for eight dimensional configurational wave function is even smaller than that of the single configurational wave function due to the electron correlation (cf. remarks below Table XX of I.).

(d) The amount of s–p promotion increases considerably if configurations involving π orbitals are taken into account.

Finally, we have examined the relation suggested by Mulliken[21])

$$\frac{n_0-n_k}{n_0}=2\frac{R_k-R_0}{R_0} \tag{33}$$

where n_0 and R_0 are the total overlap population and the equilibrium internuclear distance in the ground state, respectively, and n_k and R_k are those in the excited state. n_0 and n_k are calculated by using SCF MO's obtained for the ground state. In Table XXXVII the experimental values[12]) of $2(R_k-R_0)/R_0$ are compared with the calculated values of $(n_0-n_k)/n_0$. From this table, we can see that, contrary to the O_2 case, the relation (33) does not hold satisfactorily especially for the transition from ${}^1\Sigma_g{}^+$ to ${}^1\Sigma_u{}^+$. In O_2 case, all the SCF MO's used to calculate n_k were the occupied orbitals, while in Li_2 case, an unoccupied SCF MO such as $2\sigma_u$, which is considered unsuitable for describing excited states, enters in this calculation. In this connection we have calculated $(n_0-n_k)/n_0$ by using CI wave functions for both the ground and excited states (Table XXXVII). The result, however, becomes worse for ${}^1\Pi_u$ state, though it is improved for ${}^1\Sigma_u{}^+$ state.

§ 7. Virial Theorem

The virial theorem for a diatomic molecule can be expressed as[23])

$$T(R)=-\left\{E(R)+R\frac{\partial E(R)}{\partial R}\right\}, \tag{34}$$

where $T(R)$ is the kinetic energy of all the electrons and $E(R)$ is the adiabatic potential of the molecule. We have here intended to examine to what extent this relation is satis-

Table XXXIX. Kinetic energy T in a.u. together with ratios of computed to observed values of total energy E and dissociation energy D_e, for various approximations of Set II and $R=5.0$ a.u.

a) Experimental value of E' considered in § 7 is adopted as that of $E(Li_2)$ in shrunk core model ($E'(R=5.0)=-0.43494$ a.u.).

fied by the approximations considered in this paper.

For this purpose, $T(R)$ is separated from $E(R)$ given already and the result is shown in Tables XXXVIII and XXXIX.

Table XL. Values of $R\{\partial E(R)/\partial R\}^{a)}$ obtained by using Morse potential $U(R)$ (in a.u.).

State / R	$^1\Sigma_g{}^+$	$^1\Sigma_u{}^+$	$^1\Pi_u$
4.5	-0.0594_1	-0.1039_5	-0.1190_8
5.0	-0.0042_4	-0.0576_3	-0.0436_1
5.5	0.0297_7	-0.0212_2	-0.0026_8

a) See Eq. (34).

Further, the values of $R\{\partial E(R)/\partial R\}$, which are calculated by using the Morse function with the parameters in Table XVII, are given in Table XL.

From this table and the tables of E and T given before, we can see that the relation (34) is not satisfied well by any of all our approximations. This large disagreement seems to be originated mainly in the errors of $T(R)$ due to the unsuitableness of the adopted orbital exponent of 1s, δ_1. In order to examine this point, we have estimated the change of $T(R)$ arising from the replacement by a more suitable value of δ_1, that is $\delta_{1,\text{ best}}$. This change may essentially be approximated by that of the kinetic energy of 1s cores, which is given by $2(\delta_1{}^2{}_{,\text{ best}}-\delta_1{}^2)$. In Table XLI, this value is written, which is found by assuming $\delta_{1,\text{ best}}=2.688$ determined by Zener's rule[24]. By comparing this result with the discrepancy of relation (34), $T+E+R\{\partial E/\partial R\}$ shown in the same table, we can see that our expectation is essentially correct.

Table XLI. Correction of kinetic energy of core electrons for $^1\Sigma_g{}^+$ state.

a) See Eq. (36).
b) ΔE's are the calculated values in Table XVI.
c) From Table XL.

To study this situation, further, we have subtracted from $E(R)$ the core energy

$$2\{(\sigma_{1g}|\mathrm{h}|\sigma_{1g})+(\sigma_{1u}|\mathrm{h}|\sigma_{1u})\}+J(\sigma_{1g},\sigma_{1g})+J(\sigma_{1u},\sigma_{1u})$$
$$4J(\sigma_{1g},\sigma_{1u})-2K(\sigma_{1g},\sigma_{1u})+8/R\,, \qquad (35)$$

and from $T(R)$ the corresponding quantity. The resulting quantities are denoted by $E'(R)$ and $T'(R)$ respectively. The calculated values of $E'(R)$ and $T'(R)$ are shown in Table XLII.

From this table we can see that $T'(R)$ varies reasonably with respect to δ_2 as compared with $T(R)$, and $E'(R)$ is fairly stationary with δ_2.

As to the alternative way of eliminating the errors connected with the core electrons, we take the difference of the corresponding quantities of two states. Then the virial theorem can be expressed as

$$\Delta T=-\left\{\Delta E+\Delta\left(R\frac{\partial E(R)}{\partial R}\right)\right\}, \qquad (36)$$

where ΔT means the difference of the kinetic energy of the two states, and so on. The values of ΔT and $\Delta E+\Delta\left(R\frac{\partial E(R)}{\partial R}\right)$ for each set and R are given in Table XLIII. From this table we can see that our wave functions do not satisfy the virial theorem. We can expect, however, that if we use δ_2's for ${}^1\Sigma_u{}^+$ and ${}^1\Pi_u$ somewhat smaller than that of ${}^1\Sigma_g{}^+$, the relation (36) might be improved. This has been not important for the case of vertical excitation energies because of the nearly stationary character of $E'(R)$.

Finally we note that we could not determine the best δ_2 and R by using $E'(R)$ in Table XLII. This fact means that the subtraction of the core energy by Eq. (35) is not so accurate as to make this possible.

§ 8. Summary

In order to see the accuracy of the various approximations considered in this paper, we have calculated the ratios of the calculated values to the observed ones of the total energy E, dissociation energy D_e, and vertical excitation energy ΔE. These ratios are given in Tables XXXIX and XLIV.

Table XLIV. Ratio of computed to observed value of vertical excitation energy.

III	A	0.82	0.72	0.64	0.91	0.78	0.66
	CI	1.09	1.01	0.95	1.34	1.12	0.94

(ii) Result for Set II and R=5.0 a.u.

Method	$^1\Sigma_u^+ - ^1\Sigma_g^+$	$^1\Pi_u - ^1\Sigma_g^+$
A	0.67	0.68
HL	1.15	0.68
CI	0.99	0.99
A (shrunk core)	0.67	0.68
CI (shrunk core)	0.80	2.58

From these tables, we can see that the results are improved appreciably by taking CI into account. Above all, ΔE calculated by the relation (29) is improved excellently.

Contrary to the O_2 case, the HL approach yields a better result than the MO one, in so far as the total energy is concerned. (Compare Case 1 with Case 12.) Further, it seems clear that the effect of taking into account s–p hybridization, mixing the configurations involving π orbitals, and also semilocalization is significant.

Finally, it is shown that the relation (34) concerning the virial theorem is not satisfied well by using the wave functions here considered. This discrepancy, however, can be removed considerably by improving the orbital exponent δ_1 of the core orbital. The results obtained here will be discussed in Part III of this series of papers.

Acknowledgments

The authors have the pleasure to express their sincere thanks to Dr. T. Arai for his valuable discussions, and to Miss M. Sakamoto and Dr. T. Nakamura for informing us their unpublished results. They further appreciate the help of Dr. K. Takayanagi and Miss M. Aoyagi in the early stage of this work. They are also indebted to the Ministry of Education and to the members of Kotani Laboratory for their financial aids. Finally, they would like to thank Misses N. Mizushima, N. Sugawara, S. Noguchi, and Mrs. H. Komuro for their valuable assistance in the numerical work, and moreover, to Mrs. Y. Yuminami for her secretary service.

Structural Investigation by Means of Nuclear Quadrupole Resonance III

(Arsenic Tribromide)

By Kenji SHIMOMURA

Minami Branch, Hiroshima University, Hiroshima

(Received August 8, 1957)

The structure of $AsBr_3$ is investigated by means of nuclear quadrupole resonance at about 10°C, and is compared with Braekken's results of X-ray analysis. $AsBr_3$ has the orthorhombic symmetry, and the Br–As–Br bond angles are $99°38'\pm16'$, $99°14'\pm18'$ and $102°51'\pm13'$. The polar angles specifing the directions of the As-Br bonds with respect to the crystal axes are $(62°4'\pm13', 56°9'\pm8')$, $(64°7'\pm15', -61°46'\pm11')$, and $(61°54'\pm8', 180°50'\pm20\ )$. The bond angles are larger than those of Braekken by about 1°. The asymmetry parameter of field gradient at the bromine nucleus is about 0.04 ± 0.02. Single, double, and ionic character of As–Br bond are 61.4%, 1.2% and 37.4%, respectively, and the bond length is deduced to be 3.20 A. These results are consistent with those of X-ray analysis except the slight disagreement in the bond angles.

§ 1. Introduction

A brief preliminary report on the X-ray analysis of crystal structure of $AsBr_3$ has been published by Braekken[1]. The structure is orthorhombic with four molecules unit with the dimensions:

$$a=10.15\,kX,\ b=12.07\,kX,\ c=4.31\,kX\,.$$

Atoms are in the following special positions of $V^4\,(P2_12_12_1)$:

4 As: $x=0.300$, $y=0.215$, $z=0$,
12 Br: $x_1=-0.193$, $y_1=0.123$, $z_1=0.262$,
$x_2=0.133$, $y_2=0.123$, $z_2=-0.262$,
$x_3=0.482$, $y_3=0.123$, $z_3=-0.250$.

The structure consists of pyramidal $AsBr_3$ molecules. This report, however, is not listed in Wyckoff's Crystal Structures[2] and in the Strukturbericht[3].

On the other hand, the molecule of gaseous state has been found to have trigonal pyramidal form by the electron diffraction method; A. H. Gregg et al[4] obtained the values $100°\pm2°$, 2.36 ± 0.02 A; O. Hassel et al[5] 101°30′, 2.31 A; while M. W. Lister et al[6] $100°\pm2°$, 2.36 ± 0.04 A for the bond angle ∠Br–As–Br and As–Br bond distance, respectively.

The quadrupole spectrum of this substance has been studied by some workers[7][8] and the single line at about 60 Mc and a pair of triplets at about 170 Mc and 200 Mc have been ascribed to the As^{75}, Br^{81}, and Br^{79}, respectively, but the Zeeman and the detailed quadrupole spectrum analyses have not yet been made.

In the present experiment, the structure of $AsBr_3$ has been studied by means of NQR and the results have been compared with those of Braekken.

§ 2. Experimental Procedure

Dry powdered arsenic was introduced in small portions at a time into a flask containing bromine, and then the product was distilled from an excess of arsenic. $AsBr_3$ thus prepared was sealed in a glass cylinder with a bottom tapered to a capillary tube[9]. The single crystal which was obtained by descending the glass container slowly into water through a vertical furnace (at about 50°C) was set on a rotational axis of the crystal analyzer, which was described in some detail in a previous paper[9], so that the axis of the glass container might be approximately coincident with the rotational axis and was rotated in the hf coil of the superregenerative detector. Four different magnitudes of Zeeman fields were used, in order to avoid the misreading of the spurious signal which was built accidentally at the zero-field absorption frequency on a persistent screen of a cathode-ray oscilloscope, by the concurrence of Zeeman-splitting lines of the two sidebands on both sides of the central absorption line. Zeeman analysis was carried out on each Br^{81} line of the triplet individually at about 10°C. In order to locate two closely spaced *N. E. D.*[9], magnetic field of 350 gauss was used.

§ 3. Experimental Results

Let the triplet lines of Br^{81} be designated as ***A***, ***B*** and ***C*** from the high to the low frequency ends. The analysis shows that ***A*** and ***B*** lines are contributed by the atoms Br_{A1}, Br_{A2}, Br_{A3}, Br_{A4} and Br_{B1}, Br_{B2}, Br_{B3}, Br_{B4}, respectively. On the other hand, in any magnetic field of less than about 160 gauss ***C***-line has been found to consist of two *N. E. D.* making an angle of about 56° with each other, while the Zeeman analysis in the field of 350 gauss has revealed that each of these *N. E. D.* consists of two closely spaced *N. E. D.* The results of Zeeman analysis are shown in Fig. 1. The orientation of all *N. E. D.* are plotted on a globe on which the axis of the globe is taken to be coincident with the rotational axis of the sample (Plate 1), and the symmetry axes of the crystal are easily found from the symmetrical distributions of *N. E. D.*

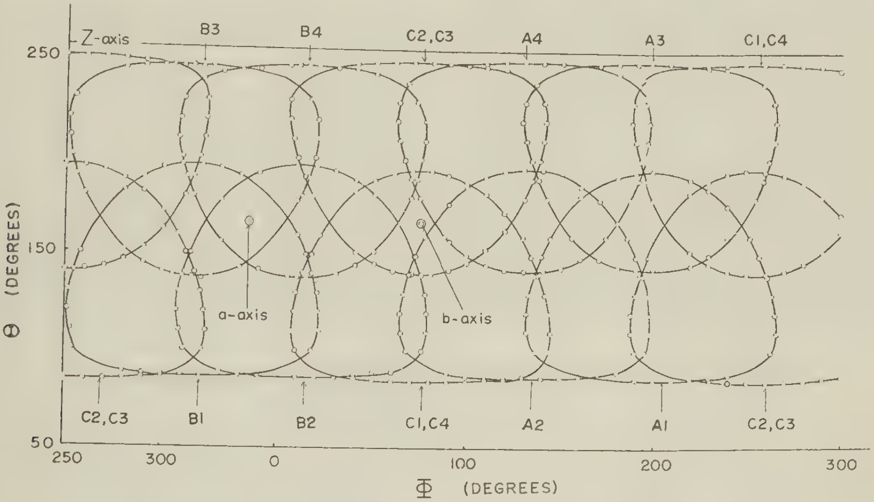

Fig. 1. Zerosplitting-direction patterns of Zeeman lines of $AsBr_3$. Θ, Φ are polar angle specifing zerosplitting-direction with respect to the orthogonal coordinate axes *XYZ* fixed to the sample. A1, A2, etc., represent the zerosplitting-directions of Zeeman lines at the nuclei Br_{A1}, Br_{A2}, etc., respectively. The closed contours which are labeled as C1, C4; and C2, C3 represent the mean directions of zerosplitting at the nuclei Br_{C1}, Br_{C4}; and Br_{C2}, Br_{C3} respectively.

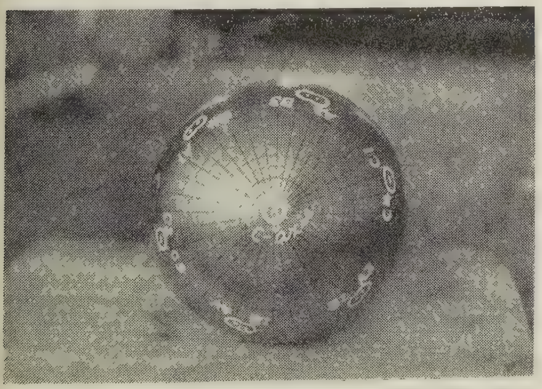

Plate 1. Plotting of directions of z-axes of field gradients on a globe. A1, A2, etc., represent the directions of the z-axes at the nuclei Br_{A1}, Br_{A2}, etc., respectively.

The magnitudes of polar angles (Θ, Φ) specifing the bond directions of As–Br_A, As–Br_B, and As–Br_C with respect to the crystal axes are (62°4′±13′, 56° 9′±8′), (64° 7′±15′, 61°46′±11′), and (61°54′±8′, 180°50′±20′), respectively. The bond angles between all *N. E. D.* are listed in Tabe I where the angle in parenthesis is supplementary angle of the other one. This duality of the choice of the bond angle is ascribed to the fact that the Zeeman analysis cannot distinguish between positive and negative directions of the z-axes of field gradient, therefore, we may assign either of two cases, i.e., α and $180°-\alpha$, to the bond angle.

* See reference 10.

The value of η obtained from the zero-splitting angles[9] for all directions is estimated 0.04 ± 0.02. The x-axis of field gradient tensor at the Br$_C$ nucleus has been found to lie in a plane containing both the z-axis and c-axis.

§ 4. Discussions

The number of resonance lines of As^{75} and Br^{81} is 1 and 3, respectively, hence the possible atomic arrangements are given in Table II from the pure quadrupole spectrum analysis[10][11], where n_i is the number of non-equivalent positions resonant atoms in a molecule belonging to the ith group, one of N sorts of groups of crystallographically non-

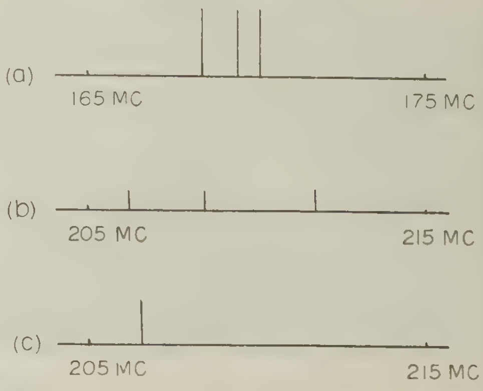

Fig. 2. Pure quadrupole spectra of Br^{81} and I^{127} of AsBr$_3$ and AsI$_3$.
(a) AsBr$_3$ (b) AsI$_3$ (at 383°K) (c) AsI$_3$ (at 300°K).

equivalent molecules in a unit-cell, and p_{ij} is the number of atoms belonging to the jth positions, i.e., one of the n_i nonequivalent ones, in that molecule.

Since the cases $N=2$ and $N=3$ are impossible for As^{75}, the possible case is $N=1$, $p_{11}(As)=1=p'_{11}(Br)=p'_{12}(Br)=p'_{13}(Br)$; each atom in $AsBr_3$ molecule has the same number of equivalent positions in a unit-cell, and the triplet line of Br^{81} are ascribed to the three bromine atoms in one molecule.

As Fig. 2 shows, the resonance spectrum for each bromine isotope is composed of three closely spaced lines and the spacing parameter⁹⁾ Δu^* for these lines is 2.7×10^{-3}, so the existence of predominantly interacting partner molecule is not very obvious in this case. In other words, we may safely conclude that the three bromine atoms in one molecule have nearly the same bond character.

While, through the Zeeman analysis we may assign the crystal to the orthorhombic symmetry class since four *N. E. D.*¹²⁾ are possible only in the orthorhombic, tetragonal or cubic symmetry class, and moreover, the fourfold symmetrical arrangements of *N. E. D.* do not exist in this case. This symmetry is consistent with that of the exterior of the crystal.

On the other hand, Kojima et al⁷⁾ have found that the pure quadrupole spectrum of of AsI_3 above 90°C has triplet lines and suggested that the crystal has the similar structure to that of $AsBr_3$ which shows a triplet spectrum, but taking the following facts into account we may deduce that their structures are somewhat different from each other: (1) their spectra have somewhat different features (Fig. 2); (2) in AsI_3 the value of η is of the order of 0.12, while that of $AsBr_3$ is smaller (0.04); (3) since the values for η and the resonance frequencies of iodine nuclei of high-temperature phase AsI_3 are almost equal to those of low-temperature one, the bond character of iodine atom may be almost the same in the two phases, so the resonance frequency of As atom, though it is not yet known, is perhaps equal to that observed in low-temperature phase (about 110 Mc⁸⁾),** whereas that of $AsBr_3$ is 62 Mc⁷⁾⁸⁾ and is appreciably different from that of AsI_3.

However, we must examine if such strong intermolecular covalent bonding as suggested by Kojima et al⁷⁾ in the case of AsI_3 in which the z-axis of field gradient at the iodine nucleus is perpendicular to the two As-I bond axes may be possible in our case. As Plate 1 shows, the z-axes of Br_A, Br_B, and Br_C nuclei are distributed about one of the crystal axis almost exactly with threefold symmetry character. Therefore, in order to interpret this fact in terms of the model in which, as Fig. 3 shows, the bromine atom is equally bonded to the two neighbouring As atoms, taking into consideration of similarity of bonding character of three bromine atoms in the molecule, we must have the three nonequivalent bromine atoms and nearest neighbouring three equivalent As atoms nearly at threefold symmetrical positions around the central As atom. However, since the

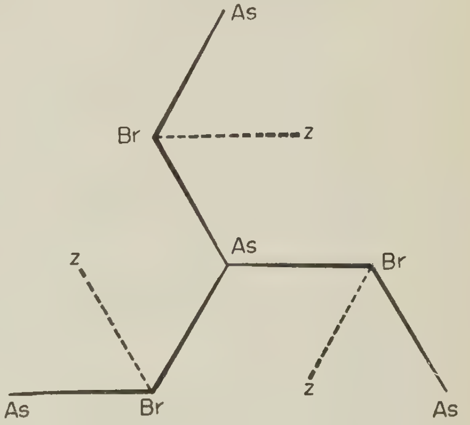

Fig. 3. The configuration of As and Br atoms which satisfies the distribution of the z-axes of field gradient which is shown in Plate 1 when the Br atom is assumed to be equally bonded to the two neighbouring As atoms.

---

* Δu for $SbBr_3$ and $AlBr_3$ are 2.20×10^{-2} and 4.34×10^{-2}, respectively. $AlBr_3$** has been known to consist of dimeric molecules. $SbBr_3$ at 77°K may have some predominantly interacting partner molecule. Distinct, moderate, and indistinct existence of such partner molecule can be infered from the values of Δu of the order of 10^{-2}, 10^{-3} and 10^{-4}, respectively in AB_n type molecule, where A and B denote the nonresonant and resonant atoms, respectively.

** See reference 2.

** Note added in proof: Recently S. Ogawa observed the As quadrupole spectrum at about 32 Mc at room temperature.

crystal has the orthorhombic symmetry, we cannot expect the threefold symmetrical configuration of equivalent points about an axis which is nearly parallel to one of the crystal axis, therefore, the bonding which is found in the case of AsI_3 does not exist in this case.

On the other hand, the possibility of deviation of the direction of z-axis of field gradient from the bond axis due to moderate intermolecular covalent bonding[13] such as in I_2 is practically neglected, because in such case the value of η is expected to be large (in I_2 the deviation angle[14] is about 30′ and $\eta=0.16$).

From these considerations we may safely assume that the direction of the z-axis of field gradient is coincident with the bond axis as is the case with common substances in which the nuclear quadrupole spectra have been observed. Since the free molecule of $AsBr_3$ has been found to consist of an trigonal pyramid, one may expect that this molecule has the similar form in the solid state also. Therefore, if we take account of the fact that the bond angle of the gaseous molecule is about 100°, it may be concluded that Br_{A1}, Br_{B1}; Br_{A2}, Br_{B2}; etc., belong to each molecule, in which $\angle Br_A\text{–}As\text{–}Br_B$ are equal to 99°38′±16′, since, as has been shown in the above discussion, the three bromine atoms forming the molecule must be made up of three atoms, each of which is picked up from the Br_A, Br_B and Br_C groups in Table I, respectively.

Unfortunately, in this case it is difficult for us to determine which group of $Br_{A1}Br_{B1}$ and $Br_{A4}Br_{B4}$ should contain the Br_{C1} atom on the basis of the criterion of similarity of molecular structure in both states of solid and gas, since Br_{C1}–As makes nearly equal angles 101°32′ and 102°48′ with As–Br_{A1} and As–Br_{A4}, respectively (it will be shown in § 5 that Br_{A1}, Br_{B1}, Br_{C4}; Br_{A2}, Br_{B2}, Br_{C3}; etc., construct their own molecules). But in any case the applicable bond angles ∠Br–As–Br, which are shown in Gothic type in Table I, are nearly equal to that of the gaseous molecule, and the above-mentioned threefold symmetrical arrangement of z-axes of the field gradient is shown to be due to this pyramidal molecule. But these bond angles are larger than the value 87° or 93° which was suggested by Kojima et al.[7]

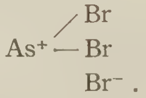
The slight asymmetry of the trigonal pyramid indicates the existence of intermolecular interaction, but the facts that the bond angles in the solid state are nearly equal to that of the gaseous molecule and that the value of η is small suggest that the intermolecular interaction is weak.

If we assume that the origin of η is due to the double bond character of As–Br bond, the fractional importance of ionic, single, and double bond character; β, $1-\beta-\gamma$, and γ, respectively, can be obtained from the following equations[15]:

$$U_p=(1-\beta-\gamma)(1-\alpha)+\left(\frac{1}{2}-\alpha\right)(1+\mathcal{E})\gamma$$

$$\eta=\frac{3\gamma(1+\mathcal{E})}{2U_p}\,, \qquad (1)$$

where α is the amount of s-hybridization[16] of the p_σ-bond, $\mathcal{E}$ is a correction[16] for the change in screening caused by the charge and U_p is the number of unbalanced p-electron[17] of the resonant atom (which is obtained from the observed resonance frequency, the value of η, and the atomic beam measurement). Introducing the value $\alpha=0.15$[16], $\mathcal{E}=0.15$[16], $\eta=0.04$, and $U_p=405.4/769.6=0.527$, one obtains 61.4%, 1.2% and 37.4% for the amount of single, double, and ionic bond character, respectively. Therefore we may conclude that the most predominant resonant structure is written as



Introducing the single and double covalent radii for Br and As with Schomaker-Stevenson correction for ionic character into Pauling's formula[17], one obtains 2.30 A for As–Br bond distance.

§ 5. Comparison with the Results of X-ray Analysis

Comparing the values of (Θ, Φ) specifing the directions of As–Br′, As–Br″, and As–Br‴ obtained from the X-ray analysis (Fig. 4) with those for As–Br_A, As–Br_B, and As–Br_C which have been studied by the Zeeman analysis, we may conclude that Br_A, Br_B, and Br_C, correspond to Br′, Br″, and Br‴, respectively (Table III), and the bond angles which are obtained from the Zeeman and

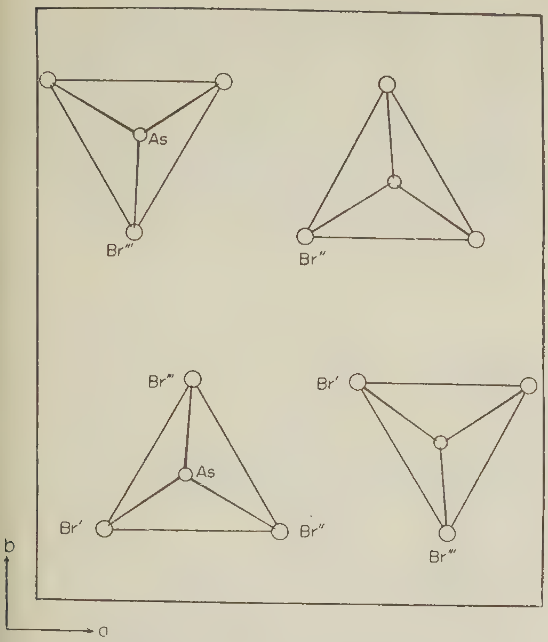


Fig. 4. The arrangement of AsBr$_3$ molecules (after Braekken[1]).

X-ray analyses are listed in Table IV. The directions of As–Br bonds with respect to the crystal axes which have been studied in this experiment are shown in Fig. 5. The bond angles obtained from Braekken's data are smaller than our values by about 1°. This discrepancy exceeds our experimental errors. However, except the slight disagreement of the bond angles, all other data including the bond distances and the directions of the principal axes of field gradient at the bromine nucleus seem to be nearly consistent with the results of the X-ray analysis. So we may conclude that the crystal analysis by Braekken is considerably exact.

In our case, we found that the c-axis of the crystal was almost coincident with the rotation axis of the sample (Plate 1), that is, with the axis of the glass container of the sample. This means that the crystal grows up most easily along the direction of the c-axis.

Appendix

Resolving Power in the Zeeman Analysis

When two *N. E. D.* make small angle with each other, their zerosplitting cones also come so close together that we cannot identify these directions using a weak magnetic field.

Now for simplicity, let us consider the case of an axially symmetric electric field. When one of the z-axes of field gradients satisfies the zerosplitting condition, the resonance frequencies of Zeeman lines corresponding to the other nonequivalent direction ν_{I}, ν_{II}, ν_{III} and

ν_{IV} between the levels $m=\pm 3/2$ and $m'=\pm 1/2$ are given in the following formulas[10]:

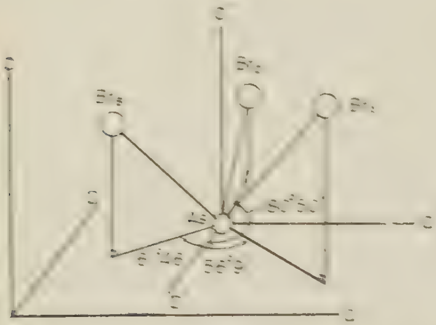

Fig. 5. The orientation of $AsBr_3$ molecule with respect to the crystal axes which has been studied through the Zeeman analysis. $As\text{-}Br_A$, $As\text{-}Br_B$, $As\text{-}Br_C$ orient at the angles 62°4', 64°7', 61°54', respectively, to the c-axis.

$$\nu_{I,II}=\nu_Q\pm\frac{3}{2}\frac{\mu_I H}{Ih}\cos\theta \pm\frac{1}{2}\frac{\mu_I H}{Ih}\sqrt{\left(I+\frac{1}{2}\right)^2\sin^2\theta+\cos^2\theta}$$

$$\nu_{III,IV}=\nu_Q\pm\frac{3}{2}\frac{\mu_I H}{Ih}\cos\theta \mp\frac{\mu_I H}{2Ih}\sqrt{\left(I+\frac{1}{2}\right)^2\sin^2\theta+\cos^2\theta} \tag{2}$$

where ν_Q is the resonance frequency in the absence of external magnetic field, μ_I and I are the magnetic moment and spin of the resonant nucleus, respectively, h is Planck's constant, and θ is the angle between the z-axis of field gradient and the external magnetic field H.

Since the resonance line has finite half maximum width $\Delta\nu$, the frequency difference between the inner component of Zeeman lines and zerosplitting one must be larger than $\Delta\nu$ in order to clearly locate the zerosplitting line. Consequently, the resolving power $\Delta\theta$ for Br^{81} can be defined as the difference between the zerosplitting angle 54°44' and θ which satisfies the following equations:

$$\left.\begin{aligned}\Delta\nu&=\frac{\xi H}{2}\left(3\cos\theta-\sqrt{4-3\cos^2\theta}\right)\\ \xi&=\frac{2\mu_I}{3h}\end{aligned}\right\} \tag{3}$$

The minimum value of magnetic field required in order to locate the two $N.E.D.$ of Br^{81} which make the angle $\Delta\theta$ with each other is given in Fig. 6. Eqs. (3) can also be applied to the study of zerosplitting near the overlapping area of nonequivalent zerosplitting cones. The above estimation has been found to be valid in our case through the study of zerosplitting in such region which is most convenient for testing the relation.

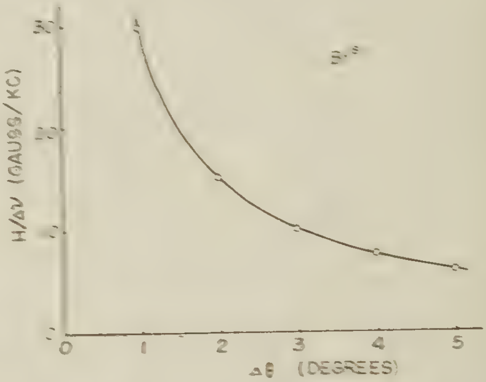

Fig. 6. The relation between resolving power $\Delta\theta$ and magnetic field which is required to discriminate two $N.E.D$.

Of course, we may locate the zerosplitting direction exactly in the area in which the zerosplitting cone situates far from the other one, since the orientation of maximum intensity of zerosplitting line can be observed without the disturbance of Zeeman lines corresponding to the other $N.E.D$.

On the Viscoelasticity and Complex Dielectric Constant in the Presence of an Electric Field and a Shearing Laminar Flow in Solution of Macromolecules

By Nobuhiko SAITÔ and Tomokazu KATO

Department of Applied Physics, Waseda University, Tokyo

(Received September 6, 1957)

The effect of an electric field on the intrinsic viscoelasticity and the effect of shearing laminar flow on the dielectric properties of dilute solutions are calculated, based on the model of a spheroidal macromolecule with dipole moment along its symmetry axis. It is shown that the intrinsic viscosity increases proportionally to the square of the applied electric field and the dielectric constant increases proportionally to the square of the velocity gradient. Simple thermodynamical considerations are given.

§ 1. Introduction

In recent years some attentions have been directed to the cross phenomena in solution of macromolecules. Of course, the most familiar cross phenomenon may be flow birefringence or Maxwell effect. Usually no birefringence can be observed without laminar flow, however, the phenomenon is rather simple because the light or the electromagnetic field can be considered not to interact with the movement of particles in the flow field. We may cite as similar instances the effect of an electric field[1] or a streaming flow[2] on the light scattering. In this paper we discuss the cross phenomena between electric field and streaming laminar flow in solution of polar macromolecules, i.e., the effect of the electric field on the intrinsic viscosity and the effect of the velocity gradient of flow on the dielectric properties of solution of polar molecules. From the outset we can surmise that each field of the two can never interact in the first order of another field from the Curie's law[3] on cross phenomena, because the electric field is of vector (first order tensor) character, while the velocity gradient is of the second order tensor character. We can, however, expect that the interactions are to be found in the second order of the strengths of the fields. In effect, Andrade et al[4],[5],[6] showed that the viscosity of liquids of polar molecules increases proportionally to the square of the applied electric field.

Onsager[7] demonstrated the so-called reciprocal relations between the coefficients of first order interaction, but we have nothing general between the coefficients of the second order interaction. We tried to find in vain any simple relation between these coefficients of the second order interaction.

On almost finishing this study, we are informed by Dr. E. Wada of Scientific Research Institute that a similar investigation was carried out by Peterlin[8]. His model is very similar to ours, but the detailed calculation is limited to the intrinsic viscosity of dumbbell molecules in two-dimensional case and nothing is said about the cross phenomenon of irreversible processes.

§ 2. Model and Applied External Forces

It may be most natural to adopt as a model of macromolecules the necklace of pearls connected by bonds of definite length or by Hookian springs. The former was adopted by Kirkwood[9] and his theory is considered to be the most rigorous statistical mechanical theory of irreversible process in solutions of macromolecules. However, the detailed calculations are very tedious and no definite conclusions can be drawn without rather drastic simplifications. The latter, Hookian spring model, proposed first by Rouse[10], was extended with success by Nakada[11] and Zimm[12] to the discussions of the mechanical and electrical relaxation phenomena in solutions or amorphous solids. This model may be seen as the most tractable and preferable, however, as Zimm pointed out, the nonlinearity can not be obtained in simple treatment. For this reason, we take up a spheroidal model of macromolecules, the intrinsic viscosity of which was treated by one of the authors[13] several years ago. Thus our model of polar macromolecules is a spheroidal rigid particle with principal axes of length $2a_1$, $2a_2=2a_1$ and $2a_3$, and has a permament dipole moment μ along the symmetry axis a_3. Let (x, y, z) and (ξ, η, ζ) be rectangular coordinate systems referred to the axes fixed in space and in the particle, respectively, with common origin taken at the center of the particle. The two coordinate systems are connected by an orthogonal transformation matrix A whose components are expressed in terms of the Eulerian angles (θ, ϕ, ψ) as follows

$$A=(a_{ij})=\begin{pmatrix} \cos\phi\cos\theta\cos\psi-\sin\phi\sin\psi & -\cos\phi\cos\theta\sin\psi-\sin\phi\cos\psi & \cos\phi\sin\theta \\ \sin\phi\cos\theta\cos\psi+\cos\phi\sin\psi & -\sin\phi\cos\theta\sin\psi+\cos\phi\cos\psi & \sin\phi\sin\theta \\ -\sin\theta\cos\psi & \sin\theta\sin\psi & \cos\theta \end{pmatrix} \tag{2.1}$$

Then we have

$$\boldsymbol{r}=A\boldsymbol{s} \quad \text{or} \quad \boldsymbol{s}=A^{-1}\boldsymbol{r}. \tag{2.2}$$

where

$$\boldsymbol{r}=\begin{pmatrix} x \\ y \\ z \end{pmatrix} \quad \text{and} \quad \boldsymbol{s}=\begin{pmatrix} \xi \\ \eta \\ \zeta \end{pmatrix}.$$

The solution of macromolecules under consideration is assumed to be so dilute that particles suspended in it behave independently, i.e., dipolar, hydrodynamical and other interactions among particles are neglected. The solution is assumed to be exerted simultaneously by a shearing force and an electric field. The former makes the fluid in motion in the direction of positive y-axis with velocity gradient g along x-axis, and the latter is applied in the direction parallel to x-axis. Then the original velocity of flow $\boldsymbol{v}^0$ in the absence of particles and the intensity of the electric field $\boldsymbol{E}$ are given in (x, y, z)-system, respectively, as follows

$$\boldsymbol{v}^0=G\boldsymbol{r}, \quad G=\begin{pmatrix} 0 & 0 & 0 \\ g & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \tag{2.3}$$

$$\boldsymbol{E}=(E,\ 0,\ 0), \tag{2.4}$$

while in (ξ, η, ζ)-system they are given by

$$\boldsymbol{u}^0=(A^{-1}GA)\boldsymbol{s}, \tag{2.3'}$$

$$\boldsymbol{E}=(a_{11}E,\ a_{12}E,\ a_{13}E). \tag{2.4'}$$

The shearing rate in (2.3′) is divided into symmetric or pure shearing-rate part and antisymmetic or rotational part, which are denoted by $H=(h_{ij})$ and $O=(o_{ij})$, respectively,

$$\boldsymbol{u}^0=H\boldsymbol{s}+O\boldsymbol{s},$$

$$\left.\begin{aligned} H=(h_{ij})&=\frac{1}{2}(A^{-1}GA)+\frac{1}{2}(A^{-1}GA)', \\ O=(o_{ij})&=\frac{1}{2}(A^{-1}GA)-\frac{1}{2}(A^{-1}GA)', \end{aligned}\right\} \tag{2.5}$$

where the primed matrices are transposed ones.

The equation of motion for the rotatory motion of particles under these fields is

$$\frac{d\boldsymbol{M}}{dt}=\boldsymbol{L}+\boldsymbol{\mu}\times\boldsymbol{E}, \tag{2.6}$$

where $\boldsymbol{M}$ is the angular momentum of the particle and the two terms of the right-hand side $\boldsymbol{L}$ and $\boldsymbol{\mu}\times\boldsymbol{E}$ are respectively the moments of forces exerted by the flowing fluid and by the electric field upon the particle.

The components of $\boldsymbol{L}$ are given in (ξ, η, ζ)-system by Jeffery,[14]

$$\begin{aligned}
L_\xi &= c_1\{-ph_{23}+(o_{32}-\omega_\xi)\}\,, \\
L_\eta &= c_1\{ph_{13}+(o_{13}-\omega_\eta)\}\,, \\
L_\zeta &= c_3(o_{21}-\omega_\zeta)\,, \\
c_1 &= \frac{16\pi\eta(a_1^2+a_3^2)}{3(a_1^2\alpha_0+a_3^2\gamma_0)}\,, \\
c_3 &= \frac{16\pi\eta}{3\alpha_0}\,, \\
p &= \frac{a_3^2-a_1^2}{a_3^2+a_1^2}\,,
\end{aligned} \tag{2.7}$$

where c_1 and c_3 are the friction constants of rotatory motion of an ellipsoid about its principal axes and η is the coefficient of viscosity of the solvent. α_0 and γ_0 are the constants whose numerical values can be evaluated when a_1 and a_3 are given. Generally, we must add a fluctuation force due to thermal agitation of the liquid, but we disregard it here because we can take this effect into consideration through diffusion equation. Ignoring the inertia effect, we put (2.6) equal to zero, then we can immediately determine the angular velocity of particle, substituting (2.7) into (2.6), with the result

$$\begin{aligned}
\omega_\xi &= o_{32}-ph_{32}+\frac{\mu E}{c_1}a_{12}\,, \\
\omega_\eta &= o_{13}+ph_{13}+\frac{\mu E}{c_1}a_{11}\,, \\
\omega_\zeta &= o_{21}\,,
\end{aligned}$$

or

$$\begin{aligned}
\dot\theta &= \frac{pg}{2}\sin 2\phi\sin\theta\cos\theta+\frac{\mu E}{c_1}\cos\phi\cos\theta\,, \\
\dot\phi &= \frac{pg}{2}\cos 2\phi+\frac{g}{2}-\frac{\mu E}{c_1}\frac{\sin\phi}{\sin\theta}\,, \\
\dot\psi &= -\frac{pg}{2}\cos\theta\cos 2\phi+\frac{\mu E}{c_1}\frac{\cos\theta\sin\phi}{\sin\theta}\,.
\end{aligned} \tag{2.8}$$

§ 3. Diffusion Equation

The diffusion equation which determines the time evolution of distribution function of the orientation of the particles under the external forces can be written down at once following the general theory of Brownian motion[9], as follows

$$\frac{\partial\rho}{\partial t} = -\frac{D}{\sin\theta}\left\{\frac{\partial}{\partial\theta}(j_\theta\rho\sin\theta)+\frac{\partial}{\partial\phi}(j_\phi\rho\sin\theta)\right\}, \tag{3.1}$$

$$\begin{aligned}
j_\theta &= \dot\theta - D\frac{\partial}{\partial\theta}\log\rho\,, \\
j_\phi &= \dot\phi - \frac{D}{\sin^2\theta}\frac{\partial}{\partial\phi}\log\rho\,, \\
j_\psi &= \dot\psi + \frac{D\cos\theta}{\sin^2\theta}\frac{\partial}{\partial\phi}\log\rho\,,
\end{aligned} \tag{3.2}$$

where $D=kT/c_1$ is rotatory diffusion constant. The flux j_ψ vanishes in (3.1) since our model is symmetric about its third axis.

Suppose that the external driving forces vary sinusoidally with time,

$$g=g_0\cos\omega_g t\,, \quad E=E_0\cos\omega_e t\,, \tag{3.3}$$

and the influences of these forces upon the orientation of molecules are small enough to be considered as the perturbations upon the equilibrium distribution $1/4\pi$. Hence we expand the solution of (3.1) in powers of $(\mu E_0/kT)$ and $(g_0c_1/2kT)$,

$$\begin{aligned}
\rho &= \frac{1}{4\pi}\left[1+\sum_{i,j,l,m}\left(\frac{\mu E_0}{kT}\right)^i\left(\frac{g_0c_1}{2kT}\right)^j {}_{ij}f_l^{(m)}(t)P_l^{(m)}(\cos\theta)\begin{matrix}\cos m\phi\\ \sin m\phi\end{matrix}\right] \\
&= \frac{1}{4\pi}\Big[1+\left(\frac{\mu E_0}{kT}\right)_{10}f_1^{(1)}(t)P_1^{(1)}(\cos\theta)\cos\phi+\left(\frac{g_0c_1}{2kT}\right)_{01}f_2^{(2)}(t)\,P_2^{(2)}\sin 2\phi \\
&\quad +\left(\frac{\mu E_0}{kT}\right)^2\{{}_{20}f_2^{(2)}(t)P_2^{(2)}(\cos\theta)\cos 2\phi+{}_{20}f_2^{(0)}(t)P_2(\cos\theta)\} \\
&\quad +\left(\frac{g_0c_1}{2kT}\right)^2\{{}_{02}f_2^{(0)}(t)P_2(\cos\theta)+{}_{02}f_4^{(0)}(t)P_4(\cos\theta)+{}_{02}f_2^{(2)}(t)P_2^{(2)}(\cos\theta)\cos 2\phi \\
&\quad +{}_{02}f_4^{(4)}(t)P_4^{(4)}(\cos\theta)\cos 4\phi)\} \\
&\quad +\left(\frac{\mu E_0}{kT}\right)\left(\frac{g_0c_1}{2kT}\right)\{{}_{11}f_1^{(1)}(t)P_1^{(1)}(\cos\theta)\sin\phi+{}_{11}f_3^{(1)}(t)P_3^{(1)}(\cos\theta)\sin\phi \\
&\quad +{}_{11}f_3^{(3)}(t)P_3^{(3)}(\cos\theta)\sin 3\phi\}+\cdots\Big]\,,
\end{aligned} \tag{3.4}$$

where $P_l^{(m)}(\cos\theta)$ denotes Legendre's associated function. The coefficients ${}_{ij}f_l^{(m)}(t)$'s are given as the real part of the following formulae,

$$ {}_{10}f_1^{(1)};\quad \frac{\exp(i\omega_e t)}{1+i\omega_e/2D} \qquad\qquad {}_{01}f_2^{(2)};\quad \frac{p}{6}\,\frac{\exp(i\omega_g t)}{1+i\omega_g/6D} $$

$$ {}_{20}f_2^{(0)};\quad -\left[\frac{1}{6}+\frac{\exp(2i\omega_e t)}{12\left(1+\dfrac{i\omega_e}{3D}\right)\left(1+\dfrac{i\omega_e}{D}\right)}\right] $$

$$ {}_{20}f_2^{(2)};\quad \left[\frac{1}{12}+\frac{\exp(2i\omega_e t)}{24\left(1+\dfrac{i\omega_e}{3D}\right)\left(1+\dfrac{i\omega_e}{D}\right)}\right] $$

$$ {}_{02}f_2^{(0)};\quad -p^2\left[\frac{1}{21}+\frac{\exp(2i\omega_g t)}{42\left(1+\dfrac{i\omega_g}{3D}\right)^2}\right] $$

$$ {}_{02}f_4^{(0)};\quad p^2\left[\frac{1}{70}+\frac{\exp(2i\omega_g t)}{140\left(1+\dfrac{i\omega_g}{3D}\right)\left(1+\dfrac{i\omega_g}{10D}\right)}\right] $$

$$ {}_{02}f_2^{(2)};\quad -p\left[\frac{1}{36}+\frac{\exp(2i\omega_g t)}{\left(1+\dfrac{i\omega_g}{3D}\right)^2}\right] $$

$$ {}_{02}f_4^{(4)};\quad -p^2\left[\frac{1}{1680}+\frac{\exp(2i\omega_g t)}{3360\left(1+\dfrac{i\omega_g}{3D}\right)\left(1+\dfrac{i\omega_g}{10D}\right)}\right] $$

$$ \begin{aligned} {}_{11}f_1^{(1)};\quad & \frac{p}{20}\left[\frac{\exp\{i(\omega_g+\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g+\omega_e)}{2D}\right\}\left\{1+\dfrac{i(\omega_g+\omega_e)}{6D}\right\}}+\frac{\exp\{i(\omega_g-\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g-\omega_e)}{2D}\right\}\left\{1+\dfrac{i(\omega_g-\omega_e)}{6D}\right\}}\right] \\ & +\frac{3p}{20}\left[\frac{\exp\{i(\omega_g+\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g+\omega_e)}{2D}\right\}^2}+\frac{\exp\{i(\omega_g-\omega_c)\,t\}}{\left\{1+\dfrac{i(\omega_g-\omega_e)}{2D}\right\}}\right] \end{aligned} $$

$$ \begin{aligned} {}_{11}f_3^{(1)};\quad & \frac{p}{360}\left[\frac{\exp\{i(\omega_g+\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g+\omega_e)}{6D}\right\}\left\{1+\dfrac{i(\omega_g+\omega_e)}{12D}\right\}}+\frac{\exp\{i(\omega_g-\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g-\omega_e)}{6D}\right\}\left\{1+\dfrac{i(\omega_g-\omega_e)}{2D}\right\}}\right] \\ & -\frac{p}{90}\left[\frac{\exp\{i(\omega_g+\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g+\omega_e)}{12D}\right\}\left\{1+\dfrac{i(\omega_g+\omega_e)}{2D}\right\}}+\frac{\exp\{i(\omega_g-\omega_e)t\}}{\left\{1+\dfrac{i(\omega_g-\omega_e)}{12D}\right\}\left\{1+\dfrac{i(\omega_g-\omega_e)}{2D}\right\}}\right] \end{aligned} $$

§ 4. Viscoelasticity of the Solution

The viscoelasticity of the solution is calculated along the same procedure as adopted by one of the present authors in the previous paper.[13]

Suppose two plates, parallel to yz-plane and separated at a distance $2h$ in the fluid, by means of which we can apply the shearing force and electric field simultaneously upon the fluid. The decrease of effective velocity gradient $g-g_{eff}$ upon adding macromolecules into the pure solvent is given by[13]

$$g-g_{eff}=\frac{16\pi N}{3g}\int\rho\biggl\{\frac{\alpha_0''h_{11}^2+\beta_0''h_{22}^2+\gamma_0''h_{33}^2}{\beta_0''\gamma_0''+\gamma_0''\alpha_0''+\alpha_0''\beta_0''}+\frac{h_{12}^2}{a_1^2\gamma_0'}+\frac{(\alpha_0+\gamma_0)(h_{13}^2+h_{23}^2)}{\alpha_0'(a_1^2\alpha_0+a_3^2\gamma_0)}$$
$$+\frac{(a_3^2-a_1^2)\alpha_0'+(\alpha_0-\gamma_0)}{\alpha_0'(a_1^2\alpha_0+a_3^2\gamma_0)}(h_{13}o_{13}-h_{23}o_{32})+\frac{a_1^2+a_3^2}{a_1^2\alpha_0+a_3^2\gamma_0}(o_{32}^2+o_{13}^2)+\frac{o_{21}^2}{\alpha_0}$$
$$-\frac{(a_3^2-a_1^2)h_{23}-(a_1^2+a_3^2)o_{32}}{a_1^2\alpha_0+a_3^2\gamma_0}j_\xi+\frac{(a_3^2-a_1^2)h_{13}+(a_1^2+a_3^2)}{a_1^2\alpha_0+a_3^2\gamma_0}j_\eta-\frac{o_{21}}{\alpha_0}j_\zeta\biggr\}d\Omega\,, \tag{4.1}$$

where N is number of particles per unit volume of the solution and j_ξ, j_η, j_ζ denote the fluxes with respect to the principal axes of ellipsoid connected with j_θ, j_ϕ, j_ψ by the following relation

$$\begin{pmatrix} j_\xi \\ j_\eta \\ j_\zeta \end{pmatrix}=\begin{pmatrix} \sin\psi & -\sin\theta\cos\psi & 0 \\ \cos\psi & \sin\theta\sin\psi & 0 \\ 0 & \cos\theta & 1 \end{pmatrix}\begin{pmatrix} j_\theta \\ j_\phi \\ j_\psi \end{pmatrix}. \tag{4.2}$$

Substitution of (4.3) into (4.1) making use of (2.8), (3.2) and (3.4) yields

$$g-g_{eff}$$
$$=\frac{16\pi N}{3}\int\rho\biggl[\frac{g}{4\gamma_0'a_1^2}\cos^2\theta+\biggl\{\frac{\alpha_0''+\gamma_0''}{2\alpha_0''\gamma_0'a_1^2}-\frac{2}{\alpha_0'(a_1^2+a_3^2)}\biggr\}g\sin^4\theta\sin^2\phi\cos^2\phi+\frac{g\sin^2\theta}{2\alpha_0'(a_1^2+a_3^2)}$$
$$+\frac{3\mu Ep}{4\pi kT\eta}(\sin 3\phi\sin^3\theta+\sin\phi\sin^3\theta-2\sin\theta\sin\phi)$$
$$+\frac{D(a_1^2+a_3^2)}{4(a_1^2\alpha_0+a_3^2\gamma_0)}\biggl\{(a_3^2-a_1^2)\biggl(\sin 2\theta\sin 2\phi\frac{\partial}{\partial\theta}\log\rho+2\cos 2\phi\frac{\partial}{\partial\phi}\log\rho\biggr)+2\frac{\partial}{\partial\phi}\log\rho\biggr\}\biggr]d\Omega\,, \tag{4.3}$$

where the integration must be performed over all possible orientations of particles. The first line of this equation is the term due to hydrodynamical effect calculated by Jeffery, the second is the contribution from the electric field and the last is due to the rotatoryd iffusion. The specific viscosity η_{sp} is given by

$$\eta_{sp}=(g-g_{eff})/g_{eff}\simeq(g-g_{eff})/g$$
$$=\frac{4\pi N}{9\gamma_0'a_1^2}+\frac{16\pi N}{9\alpha_0'(a_1^2+a_3^2)}-\frac{112\pi N}{45}\biggl\{\frac{\alpha_0''+\gamma_0''}{2\alpha_0''\gamma_0'a_1^2}-\frac{2}{\alpha_0'(a_1^2+a_3^2)}\biggr\}$$
$$+\biggl(\frac{\mu E_0}{kT}\biggr)^2\biggl[\frac{8\pi N}{45\gamma_0'a_1^2}-\frac{16\pi N}{45\alpha_0'(a_1^2+a_3^2)}-\frac{256\pi N}{315}\biggl\{\frac{\alpha_0''+\gamma_0''}{2\alpha_0''\gamma_0'a_1^2}-\frac{2}{\alpha_0'(a_1^2+a_3^2)}\biggr\}\biggr]{}_{20}f_2^{(0)}$$
$$+\biggl(\frac{g_0c_1}{2kT}\biggr)^2\biggl[\biggl\{\frac{8\pi N}{45\gamma_0'a_1^2}-\frac{16\pi N}{45\alpha_0'(a_1^2+a_3^2)}-\frac{256\pi N}{315}\biggl(\frac{\alpha_0''+\gamma_0''}{2\alpha_0''\gamma_0'a_1^2}-\frac{2}{\alpha_0'(a_1^2+a_3^2)}\biggr)\biggr\}{}_{02}f_2^{(0)}$$
$$+\biggl\{\frac{\alpha_0''+\gamma_0''}{2\alpha_0''\gamma_0'a_1^2}-\frac{2}{\alpha_0'(a_1^2+a_3^2)}\biggr\}\biggl(\frac{16\pi N}{945}{}_{02}f_4^{(0)}-\frac{128\pi N}{9}{}_{02}f_4^{(4)}\biggr)\biggr]$$
$$+\frac{Nc_1}{2\eta}\biggl[\biggl(\frac{\mu E_0}{kT}\biggr)^2\biggl\{\biggl(\frac{6}{7}{}_{11}f_3^{(3)}-\frac{1}{30}{}_{11}f_1^{(1)}-\frac{1}{35}{}_{11}f_3^{(1)}\biggr)+p\biggl(-\frac{4}{5}{}_{21}f_2^{(2)}+4\,{}_{21}f_4^{(2)}\biggr)\biggr\}$$
$$+\biggl(\frac{g_0c_1}{2kT}\biggr)^2\biggl(-\frac{4}{5}{}_{03}f_2^{(2)}+4\,{}_{03}f_4^{(2)}+4\,{}_{03}f_6^{(2)}\biggr)\biggr]. \tag{4.4}$$

The complex intrinsic viscosity $[\eta]$ is given by $\lim\eta_{sp}/c$, where c is the concentration of the macromolecules in grams per 100 cc of solvent. The deviation of intrinsic viscosity from non-Newtonian part in the absence of external forces depends on the square of the velocity gradient. The value of intrinsic viscosity at the extreme case of spherical model is

$$[\eta]=2.5\biggl(\frac{4\pi a^3}{3}\biggr)\bigg/100\,M\,, \tag{4.5}$$

where M is molecular weight of the macromolecule. This result does not depend on the electric field, and coincides with that of Einstein.

Recently Kirkwood and Plock[16] calculated non-Newtonian viscoelasticity in the absence of electric field.

§ 5. Polarization

We now discuss the dielectric properties of the solution. The interaction between particles and the influence of dielectric character of solvent are not taken into consideration. Then we use the same notation for the applied field and for internal field. Electric displacement $\boldsymbol{D}$ can be written as the sum of two terms, electronic part and dipolar part

$$\boldsymbol{D}=\varepsilon_\infty \boldsymbol{E}+4\pi N\langle\boldsymbol{\mu}\rangle \tag{5.1}$$

where ε_∞ denotes the dielectric constant for the applied field of the frequency of optical range, and $\langle\boldsymbol{\mu}\rangle$ is mean value of the component of dipole moment along the direction of electric field. The mean value is calculated with the distribution function $\rho(\theta, \phi, t)$. The component of dipole moment along the field is given by

$$\mu\cos(\boldsymbol{E}_\wedge\boldsymbol{\mu})=\mu\sin\theta\cos\phi\ . \tag{5.2}$$

Taking the average with respect to the orientation by means of (3.4), we obtain

$$\langle\mu\rangle=\int\mu\sin\theta\cos\phi\ \rho(\theta, \phi, t)\,d\Omega=\frac{\mu^2E_0}{3kT}\left\{{}_{10}f_1^{(1)}(t)+\left(\frac{\mu E_0}{kT}\right)^2{}_{30}f_1^{(1)}(t)+\left(\frac{gc_1}{2kT}\right)^2{}_{12}f_1^{(1)}(t)+\cdots\right\} \tag{5.3}$$

up to the third order terms of small quantities. In case of a vanishing velocity gradient g and negligible third order terms with respect to $(\mu E/kT)$, the average value (5.3) coincides with Debye's formula. The effect of the shear gradient on the polarization is not the first order of g but the second.

For the spherical model, the mean value of polarization is obtained from (5.3).

$$\begin{aligned}\langle\mu\rangle=\frac{\mu^2E_0}{3kT}\Bigg[&{}_{10}f_1^{(1)}(t)+\left(\frac{\mu E_0}{kT}\right)^2{}_{30}f_1^{(1)}(t)-\frac{1}{96}\left(\frac{gc_1}{2kT}\right)^2\Bigg\{\frac{\exp\{i(\omega_e+2\omega_g)t\}}{\left\{1+\dfrac{i(\omega_e+2\omega_g)}{2D}\right\}^2\left\{1+\dfrac{i(\omega_e+2\omega_g)}{6D}\right\}}\\&+\frac{\exp\{i(\omega_e-2\omega_g)t\}}{\left\{1+\dfrac{i(\omega_e-2\omega_g)}{2D}\right\}^2\left\{1+\dfrac{i(\omega_e-2\omega_g)}{6D}\right\}}+\frac{2\exp(i\omega_e t)}{\left(1+\dfrac{i\omega_e}{2D}\right)^2\left(1+\dfrac{i\omega_e}{6D}\right)}\\&+\frac{3\exp\{i(\omega_e+2\omega_g)t\}}{\left\{1+\dfrac{i(\omega_e+2\omega_g)}{2D}\right\}^3}+\frac{3\exp\{i(\omega_e-2\omega_g)t\}}{\left\{1+\dfrac{i(\omega_e-2\omega_g)}{2D}\right\}^3}+\frac{6\exp(i\omega_e t)}{\left(1+\dfrac{i\omega_e}{2D}\right)^3}\Bigg\}\Bigg]\ .\end{aligned} \tag{5.4}$$

The third term of this equation expresses the effect of shearing force on the polarization.

§ 6. Entropy Balance

In this section a simple thermodynamical consideration is given on the cross phenomena above discussed between electric vector force and hydrodynamical tensor force. As the system under consideration we take the solution of unit volume, making the laminar motion. Increment of energy due to the motion of viscous liquid in time dt is expressed in the form

$$du=d'Q+\boldsymbol{E}d\boldsymbol{D}/4\pi+\eta_{eff}\,g^2_{eff}\,dt\,,\qquad \eta_{eff}g_{eff}=\eta g\ . \tag{6.1}$$

Each terms of the right-hand side represent heat flow, works done by electric field and by hydrodynamical force, respectively. The second law of thermodynamics is written as

$$Tds=d'Q+T(ds)_{irr}\ .\qquad (ds)_{irr}\geq 0 \tag{6.2}$$

where $(ds)_{irr}$ means irreversible production of entropy. (6.2) and (6.1) give immediately for entropy production

$$\left(\frac{\partial s}{\partial t}\right)_{irr}=\left(\frac{\partial s}{\partial t}\right)+\frac{\boldsymbol{E}}{4\pi}\frac{\partial \boldsymbol{D}}{\partial t}+\eta_{eff}g^2_{eff}-\frac{\partial u}{\partial t}\,. \tag{6.3}$$

On the other hand we have

$$s=-Nk\int\rho\log\rho d\Omega+s'\,, \tag{6.4}$$

for the entropy from the well-known Gibbs formula, where s' means the entropy other than the orientation of macromolecules, and for the electric work from (5.1)

$$\frac{1}{4\pi}\boldsymbol{E}\frac{\partial \boldsymbol{D}}{\partial t}=\frac{\partial}{\partial t}\left(\frac{\varepsilon_\infty}{4\pi}E^2\right)+NE\int\mu\sin\theta\cos\phi\frac{\partial\rho}{\partial t}d\Omega\,, \tag{6.5}$$

and for the hydrodynamical work from (4.3) with the aid of (3.2) and (2.8) ηg multiplied by

$$\begin{aligned}g_{eff}=g-\frac{16\pi N}{3}\int\Bigg[&\left(\frac{g}{4\gamma_0'a_1^2}+\frac{g}{4\alpha_0}\right)\cos^2\theta+\left\{\frac{g(\alpha_0''+\gamma_0'')}{2\alpha_0''\gamma_0'a_1^2}-\frac{g(\alpha_0+\gamma_0)}{\alpha_0'(a_1^2\alpha_0+a_3^2\gamma_0)}\right\}\sin^4\theta\sin^2\phi\cos^2\phi\\&+\frac{g\sin^2\theta}{2\alpha_0'(a_1^2\alpha_0+a_3^2\gamma_0)}(\alpha_0\cos^2\phi+\gamma_0\sin^2\phi)+\frac{g(a_3^2-a_1^2)}{4(a_1^2\alpha_0+a_3^2\gamma_0)}\sin^2\theta\cos^2\phi\\&+\frac{(a_3^2+a_1^2)g}{4(a_1^2\alpha_0+a_3^2\gamma_0)}\sin^2\theta\Bigg]\rho\,d\Omega+\frac{16\pi N}{3}\int\frac{a_3^2+a_1^2}{4(a_1^2\alpha_0+a_3^2\gamma_0)}\\&\{p(j_\theta\sin 2\theta\sin 2\phi+2j_\phi\sin^2\theta\cos 2\phi)+2j_\phi\sin^2\theta\}+\frac{1}{2\alpha_0}(j_\phi\cos^2\theta+j_\psi\cos\theta)\Bigg]\rho\,d\Omega\,.\end{aligned} \tag{6.6}$$

The work done by hydrodynamical force is divided into three parts, the work dissipated even in the absence of macromolecules in order to maintain the velocity gradient in the solvent ηg^2, the excess work necessary after introducing macromolecules at rest in the solvent and the work required when particles are in motion expressed by the first integral in (6.6). Because our main interest is concerned with the orientation of macromolecules and the irreversible production of entropy arising from this $(\partial s/\partial t)_{irr.\ orient.}$, the last part should be retained in evaluating $(\partial s/\partial t)_{irr.\ orient.}$ by means of (6.3). Thus we put as the work done by electric force with the help of diffusion equation (3.1)

$$NE\mu\int\cos\phi\left\{\frac{\partial}{\partial\theta}(j_\theta\rho\sin\theta)+\frac{\partial}{\partial\phi}(j_\phi\rho\sin\theta)\right\}d\Omega\,, \tag{6.7}$$

and as the work done by hydrodynamical force

$$\begin{aligned}&Nc_1\int\left\{\frac{gp}{2}\left(\frac{1}{2}j_\theta\sin 2\theta\sin 2\phi+j_\phi\sin^2\theta\cos 2\phi\right)+\frac{g}{2}j_\phi\sin^2\theta\right\}\rho\,d\Omega\\&\qquad+Nc_3\int\frac{g}{2}\cos\theta(j_\phi\cos\theta+j_\psi)\rho\,d\Omega\,,\end{aligned} \tag{6.8}$$

and also we have from (6.4)

$$\left(\frac{\partial s}{\partial t}\right)_{orient.}=N\int\left\{j_\theta\left(-kT\frac{\partial\rho}{\partial\theta}\right)+j_\phi\left(-kT\frac{\partial\rho}{\partial\phi}\right)\right\}d\Omega\,, \tag{6.9}$$

making use of the diffusion equation and partial integration. Substituting these results into (6.3), we have

$$\begin{aligned}\left(\frac{\partial s}{\partial t}\right)_{irr.\ orient.}=\frac{N}{T}\int\Bigg[&j_\theta\left\{-kT\frac{\partial}{\partial\theta}\log\rho+\mu E\cos\phi\cos\theta+\frac{gp}{2}\sin 2\theta\sin 2\phi\right\}\\&+j_\phi\left\{-kT\frac{\partial}{\partial\phi}\log\rho-\mu E\sin\phi\sin\theta+\frac{gp}{2}c_1\sin^2\theta\cos\phi+\frac{g}{2}\sin^2\theta+\frac{gc_3}{2}\cos^2\theta\right\}\end{aligned}$$

$$+ j_\psi \frac{gc_3}{2}\cos\theta \Big]\rho\, d\Omega\,. \tag{6.10}$$

The coefficients of j_θ, j_ϕ and j_ψ multiplied by ρ correspond to general affinities defined in irreversible thermodynamics. When one reminds of (3.2) and (4.2) we have

$$\left(\frac{\partial s}{\partial t}\right)_{irr.} = \frac{N}{T}\int\{c_1(j_\xi^2+j_\eta^2)+c_3 j_\zeta^2\}\rho\, d\Omega \tag{6.11}$$

where c_1, c_2 $(=c_1)$ and c_3 are rotatory friction coefficients around three principal axes. This result is consistent with that of Saitô and Sugita,[15] based on simple rigid pearl necklace model, and is a complement of their discussion to spheroidal macromolecules.

§ 7. Discussions

Unfortunately we have not found any experimental report on polymer solution which is to be compared with our results. From the measurements on the viscosity of polar and non-polar liquids such as monochlorobenzene, chloroform and amyl acetate, Andrade et al[4),5),6)] observed following characteristics in liquids; the viscosities of non-polar liquids are not influenced by the presence of electric field but the viscosities of polar liquids increase proportionally with the square of the intensity of an applied electric field and the increments are proportional to the square of the frequency of the electric field. All these behaviors are in qualitative agreement with our results. Because our model can not be considered to fit for the polar liquids whose viscosities were measured by Andrade et al, we will not undertake any numerical comparison with their experiments. Peterlin[8)] treated a quite similar problem with similar model. His calculation, however, is restricted only to the effect of electric field on the viscosity of dumb-bell molecules and the detailed calculation is carried out in two-dimensional case.

In the above treatment, the interactions of the electric current and momentum flow are considered, forces generating these currents being electric field of vector character and shearing stress of tensor character. The interactions of both forces in the first order are evidently denied by Curie's law but on higher order terms with regards to the magnitude of these forces nothing can be mentioned and the interactions of higher order may take place, as is shown in our calculation. Vectors j's are axial vectors. Thus they are coupled with $\boldsymbol{\mu}\times\boldsymbol{E}$ and terms containing $g/2$ of the same tensor character as is seen in (3.2) and (2.8).

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 12, DECEMBER, 1957

On the Properties of Long-Gap Streamers

By Kanji HONDA

Department of Physics, University of Tokyo, Tokyo

(Received August 19, 1957)

The paper is a trial of systematic explanation of long-gap streamers including step-leaders of lightning discharge. The paper gives various quantities concerning streamer properties as functions of "unbroken length", and satisfactorily explains the well-known facts about streamers, that is, that stepping occurs in lightning leaders, that the mean spark gradient becomes 5 kV/cm for long gaps and so on. The theory also points out that streamer can not cause any sensible temperature rise by itself, or in other words that they can only be cold streamers.

Introduction

In the atmospheric air, long-gap sparks are initiated by filamentary, ionized paths called "streamers". They have been studied by many authors since the discovery of Lichtenberg's figure, but their nature can not be said to have been perfectly understood. On the other hand, Schonland[1)] has explored the structure of lightning discharge through his rotating-camera observation extending over a long time. One of the most interesting properties is the stepping of its initial leader which corresponds to a long-gap streamer followed by spark discharge.

Meek[2)], and then Schonland[3)] published a paper treating this step-phenomenon theoretically. Schonland's theory especially stresses that the lightning leader is nothing but a special case of ordinary long-gap streamers, and pays keen reference to the data of laboratory streamers.

According to his theory a pilot treamer, the head part of the leader, with ionizing tip field cuts its way through air with drift velocity about 10^7 cm/s and for every $10 \sim 80$ m advance of the pilot the rear part of the leader called "channel" overtakes the pilot tip with far larger velocity ($\sim 10^9$ cm/s) and then stays there until the next new step is traced by the pilot. The large channel velocity is caused by the breakdown occurring at the channel head due to the space charge of the pilot.

The present author was stimulated by Schonland's theory and tried to obtain more generalized theory as to cover any streamer breakdown of ordinary long gaps. The following paper will show that his theory, though unrefined yet, is enough to explain some well-known empirical facts about streamers as summarized ahead.

THEORY

I. General

§ 1. General View

The streamer means a filamentary, conductive path stretching from one or both of the electrodes in gas and provides a preparatory path for a spark in a long gap or in lightning discharge.

The remarkable property of the streamer is that it extends with velocity v_0 of about 10^7 cm/s in the atmospheric air carrying at its tip an ionizing field X_0 due to its own space charge, where v_0 and X_0 must have a close relation of course.

The filamentary body of the streamer is considered to contain plenty of electrons and positive ions and to be in a state of conductive plasma with weak axial field. Then there must be a charge layer of the same polarity as the streamer surrounding the plasma in order to protect it from the external field, and charge must continuously be supplied for this purpose to the freshly producing portion at the tip. Accordingly the charge q per unit length of the streamer relates to the streamer current I as

$$I = q v_0 . \qquad (1)$$

According to Schonland's observation, the initial lightning stremer called "stepped leader" remains in space longer than 0.01 second. The largest part of such a streamer must therefore be in quasi-steady state and be distinguished from the freshly produced transient part of the streamer tip. Let us call this quasi-steady long part "channel" and the transient part "pilot" hereafter in accordance with Schonland's nomenclature.

To make conditions clear, the author treats the case where a streamer of one polarity, either positive or negative, spreads toward a wide plane electrode in the air of 1 atm pressure. A lightning leader spreading toward the earth surface may be considered to be an example of such a case.

§ 2. Pilot Model

Let us first assume that the pilot has a spherical seat of ionizing field X_0 at its head and a cylindrical stem part of radius r as shown in Fig. 1 though the idea "cylindrical" must be corrected later on.

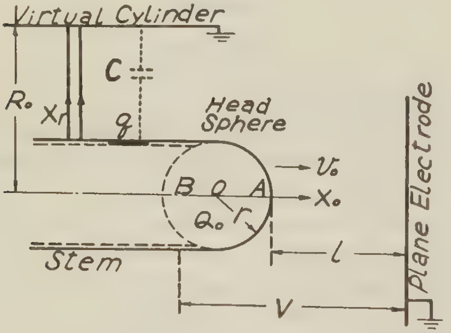

Fig. 1. Pilot model.

The velocity v_0 and the tip field X_0 are considered to be most essential for streamer progression. According to various observations v_0 does not differ much from case to case and always of the order of $(10^6 \sim 10^7)$ cm/s. So let us consider that v_0 is constant during progression and that X_0 remains constant as well.

About the stem part of the pilot we shall assume the external field X_r to be radial, or in other words that the pilot forms a cylindrical condenser with a concentric virtual cylinder of zero potential. This assumption may be allowed approximately so far as we discuss the streamer extended midway in a long gap. Then the capacity per unit length C can be expressed by

$$C = \frac{1}{2 \ln (R_0/r)}, \qquad (2)$$

where R_0 is the radius of the virtual outer cylinder. R_0 is unknown but r will after be shown to be proportional to the "unbroken length" l, that is, the distance which lies between the pilot head and the opposite electrode; and what is more, we may imagine the field configuration around the streamer to be approximately similar for different l, that is, R_0 also nearly proportional to l. Therefore we can expect that the capacity C may not be so much affected by l, and thus we shall assume it as a constant.

Let the potential of the pilot be V, then the charge per unit length q is given by

$$q = CV. \qquad (3)$$

Now we are considering the streamer which will subsequently grow to a spark, so V means the spark voltage for the unbroken length l. Then we may write V as

$$V = Kl \qquad (4)$$

in first approximation. This relation holds for the electrode voltage which is required to produce spark in a large gap, and not for the instantaneous voltage which exists between the streamer tip and the opposite electrode at spark occurrence. But if the internal gradient of the streamer be nearly equal to K of Eq. (4) as we shall discuss in § 5, the above relation can also be applicable for streamer tip voltage.

The constant K may be called the mean spark gradient for a long air gap and for 1 atm is nearly

$$K = 5 \text{ kV/cm}$$
$$= 16.7 \text{ esu/cm}. \qquad (5)$$

By the way, the introduction of C and l into equations is the most essential point of this paper. From (3) and (4) we get the relation

$$q = CKl. \qquad (6)$$

In our theory the stem part can not keep its original form, but tends to assume the final state by lateral expansion. Therefore C and q are affected by stem radius in themselves, but the effect will be shown to be so small that the above values of C and q may be used also for expanding pilot stem and the channel with an error of about 1%.

Eq. (6) shows that q varies proportional to the unbroken length l and so takes forwardly decreasing distribution along the streamer.

For an electrode-distance L the total charge

Q demanded by the bridging streamer is therefore

$$Q=\int_{l=0}^{L} q dl=\frac{1}{2}CKL^2 .$$

This expression enables us to estimate the value of C by means of Schonland's data about lightning leaders. According to him the mean values of Q and L are as follows:

$$Q=4 \text{ coul}=1.2\times10^{10} \text{ esu}$$

and

$$L=5 \text{ km}=5\times10^{5} \text{ cm} .$$

Inserting these values in the above equation we get

$$C=0.00575 \text{ esu/cm} , \tag{7}$$

and (6) can therefore be written as

$$q=0.096\, l . \tag{8}$$

§ 3. Pilot Radius

Here pilot radius r originally means that of the head-sphere, and not the radius of the pilot stem. The stem has of course the same radius at first, but subsequently expands due to its own surface field. The head-sphere must also expand outward, but for the present the author neglects its expansion and gives the following hypothetical structure to the head-sphere:

i) the radius r is not affected by the expansion of the stem.

ii) the sphere is electrically insulated from the stem, but one half of its surface is perfectly shielded by the stem plasma. (B-side in Fig. 1)

Let us assume that the charge Q_0 producing the tip field distributes uniformly on the surface of the head-sphere. Then

$$X_0=\frac{Q_0}{r^2} .$$

Now the power input IV is consumed in the work done by the hemisphere $(Q_0^2/8r^2)v_0$ and the energy storage of the freshly producing stem part $(CV^2/2)v_0$. Here V is the potential of the pilot stem referred to the opposite electrode and does not contain the drop in the channel. Then

$$IV=\frac{CV^2}{2}v_0+\frac{Q_0^2}{8r^2}v_0 ,$$

but since IV can be transformed by (1) and (3) as follows:

$$IV=qv_0V=CV^2v_0 ,$$

we get the relation

$$r=\frac{2\sqrt{C}V}{X_0}=\frac{2.53\, l}{X_0} . \tag{9}*$$

If we put $rX_0=V$ in (9), that is, if we assume the stem and the head-sphere to be euipotential, C would take a definite value 1/4, and is far larger than the value of (7). This is why the assumption (ii) is necessary.

§ 4. Channel Radius

As already mentioned, the channel is a final quasi-steady state that the pilot stem assumes after lateral expansion. Therefore the channel radius R must be larger than the pilot radius given by (9).

The condition that determines R is that outside R-cylinder the rate of electron loss is greater than the rate of electron production. Since in normal air the loss due to attachment is far greater than that due to recombination for an electron, we here consider the former only.

If Z_S is the ionizing collision frequency and β the attachment coefficient of an electron, R is determined from the condition

$$\beta=Z_S , \tag{10}$$

where Z_S implies ionization by single collision, because at the R-surface electrons would be exposed to the strong external field.

In Fig. 2 point A satisfies the condition (10) and so gives the external field intensity X_R at the surface of the channel, and consequently its radius R is determined according to the expression

$$X_R=\frac{2q}{R} . \tag{11}$$

The charge per unit length of the channel q should originally be distinguished from that of the pilot given by (3) since $R \not\fallingdotseq r$. However their difference being neglisibly small as may be inferred from the form of (2), we need not discriminate them from each other.**

In Fig. 2 β-curve was taken from Loeb's book[4] and Z_S-value from Sanders' α/p-

---

* According to (9) the charge of the head-sphere Q_0 $(=X_0r^2)$ varies with l, that is, as the sphere advances; and therefore produces another component of current. But $|dQ_0/dt|$ being 10^{-4} times as large as qv_0, we may leave Eq. (1) unchanged.

** $(q_R-q_r)/q_r$ is 1.54% for positive streamers and 0.28% for negative streamers.

values.[5] We also made a reference to von Engel and Steenbeck's formula[6] of ionizing collision frequency. From Fig. 2 we get

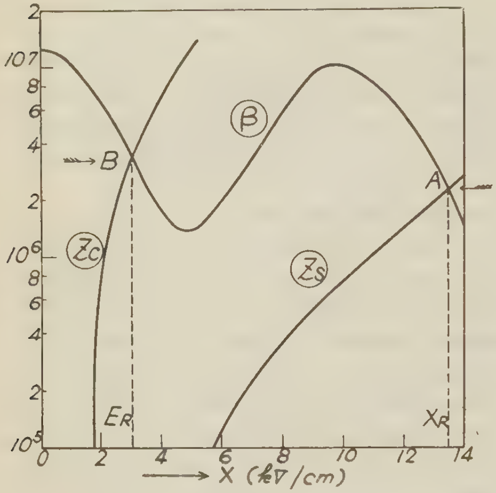

Fig. 2.

$$X_R = 13500 \text{ V/cm}$$
$$= 45 \text{ esu/cm} \qquad (11a)$$

and

$$R = 4.27 \times 10^{-3}\, l\,. \qquad (12)$$

§ 5. Internal Condition of Channel

Eq. (10) must equally hold in channel plasma because here also the balance of loss and generation of electrons is the only one probable governing condition. (Refer to B) § 14)

The channel plasma is perfectly shielded from the external field, hence in first approximation there can be only an axial field E_R required for maintenance of streamer current. However as the densities of electrons and ions are very large, E_R must be very small compared with the surface field X_R and so the point A of Fig. 2 cannot express the internal field condition by itself.

On the other hand, the existence of the relation (4) strongly suggests that K must mean some value near the internal field of the streamer channel E_R. Then, however, Z-curve will have to intersect β-curve somewhere near the minimum which occurs at 5 kV/cm as shown in Fig. 2. We can answer as follows.

Since the electron density is large and the field intensity E_R rather small in the channel, cumulative ionization must play an important role. Then Z-curve will shift toward the left in Fig. 2. As a trial if we put the metastable potential of N_2 in place of its ionization potential in Z-equation, the calculated Z-curve shown by Z_C in the figure crosses β-curve at point B near the minimum. Let us take the field of point B as E_R for the present, then from the figure

$$E_R = 3.0 \text{ kV/cm} = 10 \text{ esu/cm}\,. \qquad (13)$$

Here it is worth notice that points A and B are attained by the expanding pilot simultaneously but from opposite directions as shown by arrows in Fig. 2. Because when the pilot is expanding its surface field is decreasing while the internal field is increasing due to the decrease of the densities of electrons and ions.

Furthermore there is another point of remark. Since we are treating the case of static breakdown, voltage KL exists between the electrodes, where L denotes the electrode distance. When the streamer spreads out x cm long along the field from one electrode, the potential drop in it becomes $E_R x$. So the remaining unbroken space bears a part of voltage $(KL - E_R x)$, or nearly Kl if K and E_R have somewhat similar values. Then whatever position the streamer tip arrives at, there appears no large over- or under-voltage state and the relations (4) and (6) hold for any value of x.

However if x occurs athwart the field, under-voltage state will appear and the streamer can not help stopping unless some other circumstance energizes it, because $(KL - E_R x)$ becomes less than Kl in such a case. This explains why many branches of streamers are apt to disappear midway on their way.

II. Negative Streamer

§ 6. Negative Streamer Velocity

So far we have discussed general properties of the streamer that are common for both positive and negative polarities. We know however that positive ions can not move so swiftly as electrons; and we must take this polarity effect into account to explain the details of streamer properties.

As to the negative streamer, there is little ambiguity about the relation between X_0 and v_0, because v_0 is nothing but the drift velocity of the pilot head electrons. In this case however, electrons move in their own field, so the expression

$$v_0=\frac{1}{2}\mu X_0 \tag{14}$$

must be used instead of μX_0, where μ expresses the mobility of an electron.

The velocity v_0 may be considered to be common to all streamers of the same polarity and Schonland's value for lightning leader

$$v_0=4\times10^7\ \text{cm/s} \tag{15}$$

will be used in our calculation. Then X_0 is obtained from (14) as

$$\begin{aligned}X_0&=2.30\times10^5\ \text{V/cm}\\&=760\ \text{esu/cm}\,,\end{aligned} \tag{15a}$$

where the following value of μ is employed:

$$\begin{aligned}\mu&=350\ \text{(cm/s)/(V/cm)}\\&=1.05\times10^5\ \text{(cm/s)/(esu/cm)}.\end{aligned} \tag{15b}$$

Introducing (15a) in (9) we get

$$r=3.34\times10^{-3}\,l\,. \tag{16}$$

§7. Transition from Pilot to Channel —Stepping—of Negative Streamer

The channel has a radius larger than the pilot as obvious from comparison of (12) and (16). The pilot stem, once produced, expands laterally on account of the radial surface field. Then how much time will it take to assume the final state "channel"?

This time $\Delta\tau$ can easily be calculated as follows:

$$\Delta\tau=\int_{\rho=r}^{R}\frac{d\rho}{v_\rho}=\int_{\rho=r}^{R}\frac{d\rho}{\frac{1}{2}\mu X_\rho}\,, \tag{17}$$

where X_ρ is the surface field when the pilot stem reaches any radius ρ and given by $2q/\rho$. Whence

$$\Delta\tau=\frac{1}{2\mu q}(R^2-r^2)\,, \tag{18}$$

where q is regarded as a constant.* (Refer to §2) While the pilot expands laterally, its head advances forward, so it takes a form as shown in Fig. 3. If any abrupt change does not follow, the streamer will keep this form throughout its advance. It is more likely, however, that such steady advance is rather difficult for the streamer. The reason is as follows.

The internal space of the expanding pilot is filled with plasma, but it can hardly be neutral, because in accordance with the advance of the pilot head, continuous supply of charge is demanded by the freshly producing surface. This surface charge is of course supplied by the streamer current (1) after all, but the plasma must be its momentary source.

Moreover, electrons produce new ones on their expansion, then some of the latter must join the former. From these reasons it is most probable that the plasma of the pilot is deficient in electrons and hence has some content of positive space charge.

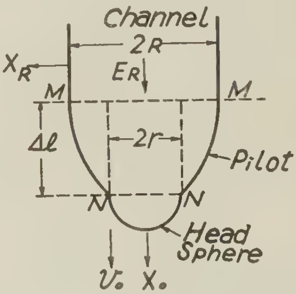

Fig. 3. Steady form of streamer tip.

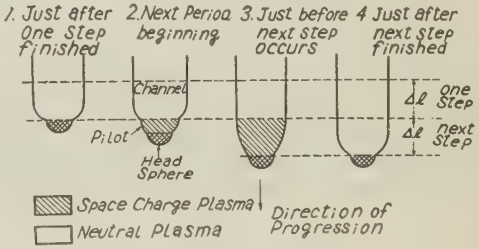

Fig. 4. Stepwise progression.

Since the channel plasma is considered to be nearly neutral, this space charge produces the strongest field at the bottom of pilot M M of Fig. 3. If this field be sufficient for enough ionization, this field disturbance must propagate through the whole pilot plasma like a moving striation and its velocity of propagation may be larger than that of pilot advance by a similar reason as for the positive streamer. (See §8)

In such a case the pilot can not keep the steady form of Fig. 3, but repeats a periodic change of form in accordance with its advance as shown in Fig. 4. This explains the stepping of the lightning initial leader and (18) gives its period. However q therein must be larger than the normal value given by (8) on account of the above mentioned reason. We assume twice the normal value as a rough estimation.

---

* The erorr due to treating q as a constant is 0.575%.

The advance of the pilot during $\Delta\tau$, that gives the step length, is given by

$$\Delta l = v_0 \Delta\tau . \tag{19}$$

III. Positive Streamer

§ 8. X_0 and r of Head-Sphere

In the case of positive streamer v_0 can not be explained by the drift motion of positive ions; because measured v_0 of the positive streamer is even greater than that of the negative streamer.

In this case electrons flow into the pilot head from the adjacent space ionizing air along their paths. The pilot head will then be surrounded by plasma and a new space charge laryer appearing at the tip of this plasma will take over the tip field X_0. Therefore the velocity of a positive streamer means the phase velocity of the ionizing seat and not the drift velocity of ions.

We shall assume a value

$$v_0 = 8 \times 10^7 \text{ cm/s} \tag{20}$$

for our calculation.

Imagine a stationary head-sphere whose center locates at O on x-axis and assume that its ionizing field reaches as far as N-sphere distant by s ahead the head center O in Fig. 5. Then the electrons which enter N-sphere will ionize M N space and a positive ion layer of some thickness Δ will appear in contact with N-surface. Midway between M and N no such a layer can appear since the space will be filled by plasma.

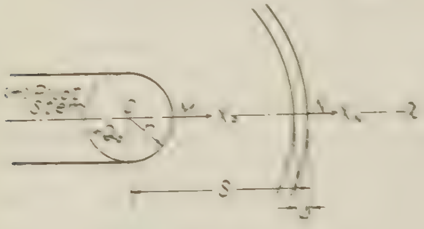

Fig. 5. Positive pilot.

If the space charge field X_N due to this ion layer becomes equal to the head-sphere field X_0, this means nothing but the advance of the pilot head M up to N. X_N takes the minimum ionizing field X_m at first and the head-sphere field X_0 at last. Then from its initial condition

$$X_m s^2 = X_0 r^2 , \tag{21}$$

and together with the relation (9) we get

$$\frac{r}{l} = \frac{X_m}{2\sqrt{CK}} \left(\frac{s}{l}\right)^2 \tag{21a}$$

and

$$X_0 = \frac{4CK^2}{X_m} \left(\frac{s}{l}\right)^{-2} . \tag{21b}$$

As X_m we shall use the value

$$X_m = 23 \text{ kV/cm} = 77 \text{ esu/cm} , \tag{22}$$

then (21a) and (21b) can be written as

$$\frac{r}{l} = 30.3 \left(\frac{s}{l}\right)^2 \tag{23a}$$

and

$$X_0 = 8.34 \times 10^{-2} \left(\frac{s}{l}\right)^{-2} . \tag{23b}$$

Since we are assuming X_0 to be independent of l as for the negative streamer, s/l must also be independent of l by (23b). Then r becomes proportional to l by (23a).

Next we shall consider about the time required by X_N for building up from X_m to X_0. If we denote it by t_0, it relates to the streamer velocity v_0 as follows:

$$v_0 t_0 = s - r . \tag{24}$$

The time t_0 is obtained in the following manner.

The field increment dX_N at N during dt is given by

$$dX_N = 4\pi e n_0 \mu X_N A dt , \tag{25}$$

where n_0 is the electron density at N before ionization; A is amplification due to ionization in Δ-space and is given by

$$A = \varepsilon^{-\int_s^{s-\Delta} \alpha dx} - 1 \sim \varepsilon^{-\int_s^{s-\Delta} \alpha dx} . \tag{26}$$

A is a function of X_N, but since Δ is expected to decrease with increasing X_N, A should change rather moderately with X_N. As a preferable form let us assume that

$$A = aX_N^{3/2} = 0.12 X_N^{3/2} . \tag{26a}$$

which gives $\Delta = 1.6$ cm for 30 kV/cm for instance.

The electron density n_0 at N-surface is conveniently assumed to decrease with increasing X_N. Put

$$n_0 = \frac{b}{X_N} . \tag{27}$$

where the constant b will be given later by (31). By virtue of (26a) and (27) we can get t_0 from (25), that is,

$$t_0=\int_{X_m}^{X_0}\frac{dX_N}{4\pi e\mu n_0 A X_N}$$

$$=\frac{1}{2\pi e\mu ab}\left(\frac{1}{X_m{}^{1/2}}-\frac{1}{X_0{}^{1/2}}\right). \qquad (28)$$

Next consider the total electron charge q_0 which enters N-hemisphere during t_0; it is given by

$$q_0=\int_0^{t_0} en_0 2\pi s^2\mu X_N dt=2\pi s^2 e\mu b t_0. \qquad (29)$$

Since, however, the charge of the head-sphere must decrease by the same amount,

$$q_0=-\frac{dQ_0}{dt}t_0=\frac{dQ_0}{dl}v_0 t_0.$$

From the relation $s/l=$constant

$$\frac{ds}{dl}=\frac{s}{l},$$

and also

$$Q_0=s^2X_m,$$

so

$$q_0=\frac{v_0X_m 2s^2}{l}t_0. \qquad (30)$$

Equating (29) and (30), we get

$$b=\frac{v_0X_m}{\pi e\mu l}. \qquad (31)$$

Put t_0 into (24) and further substitute r and X_0 therein by (23a) and (23b), then s/l will be obtained as one of the roots of the following equation:

$$x^2-3.94\times10^{-2}x+2.04\times10^{-4}=0.$$

Taking the smaller x, we get

$$\frac{s}{l}=6.1\times10^{-3}. \qquad (32)$$

From this result we can derive various quantities as follows:

$$X_0=2200\ \text{esu/cm}=660\ \text{kV/cm}, \qquad (32a)$$

$$\frac{r}{l}=1.13\times10^{-3}, \qquad (32b)$$

and

$$bl=4.87\times10^5 v_0. \qquad (32c)$$

§ 9. Transition from Pilot to Channel —Stepping—of Positive Streamer

We shall next discuss about the stepping of the positive streamer. Here also the similar calculation principle as for the head-sphere must be applied. This case is however far simpler, because the position of the limit surface, which corresponds to N-surface of Fig. 5, remains constant ($=X_m$) during expansion. So we can estimate $\Delta\tau$ by the following equation directly:

$$4\pi en_0\mu X_m\cdot\Delta\tau\cdot A=X_m.$$

This is further transformed by virtue of (26a) and (31) as

$$\Delta\tau=\frac{l}{4aX_m{}^{3/2}v_0}. \qquad (33)$$

The above estimated $\Delta\tau$ means the duration of expansion up to radius ρ_1, where the minimum ionizing field exists. We denote the $\Delta\tau$ of (33) by $\Delta\tau_1$, and putting the numerical values of X_m and a in it, we get

$$\Delta\tau_1=3.09\times10^{-3}\frac{l}{v_0}. \qquad (33a)$$

Also the limit radius ρ_1 is given by

$$\rho_1=\frac{2q}{X_m}=2.5\times10^{-3}l. \qquad (34)$$

From ρ_1 up to the final channel radius R, on the other hand, the surface continues to expand with ionic velocity $(1/2)\mu_i X$ as in the case of the negative streamer, where μ_i means ion mobility. The time required for this expansion becomes

$$\Delta\tau_2=\int_{\rho_1}^{R}\frac{d\rho}{\frac{1}{2}\mu_i X_\rho}=\frac{1}{2\mu_i q}(R^2-\rho_1{}^2). \qquad (35)$$

Assuming the value

$$\mu_i=1.5\ \text{(cm/s)/(V/cm)}=450\ \text{(cm/s)/(esu/cm)}, \qquad (36)$$

$\Delta\tau_2$ becomes as follows:

$$\Delta\tau_2=13.8\times10^{-8}l. \qquad (37)$$

For lightning leaders, $\Delta\tau_2$ becomes milliseconds or more while $\Delta\tau_1$ is of the order of microseconds. This means that a positive streamer expands rapidly up to the radius of ionization limit, but then expands very slowly. Then step period of the positive lightning leader must therefore be decided by $\Delta\tau_1$.

On the contrary, for gaps of meter length $\Delta\tau_1$ becomes negligibly small and $\Delta\tau_2$ becomes measurable order. Therefore if stepping be observed for such gaps $\Delta\tau_2$ should be taken into account.

IV. Numerical Calculation and Discussion

§ 10. Systematizing the Theory

So far we have succeeded in obtaining

various important quantities concerning the structure of the streamer. The mutual interconnections among them are shown in the following diagram Fig. 6 for the convenience of calculation.

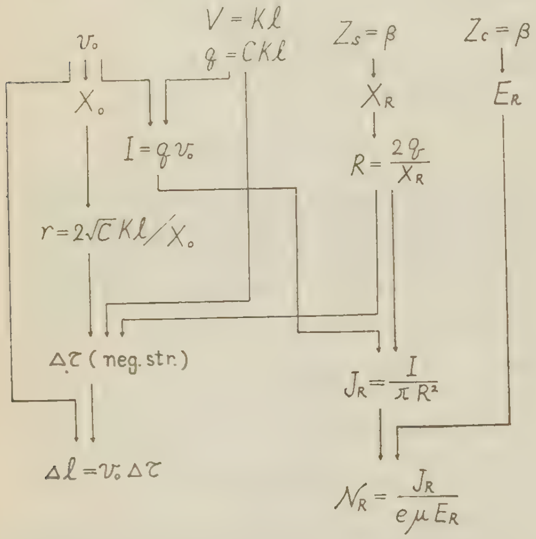

Fig. 6. Diagram showing the procedure of calculation.

In the diagram $\varDelta\tau$ is shown for the negative streamer; for $\varDelta\tau_1$ and $\varDelta\tau_2$ of the positive streamer (33) and (35) should be referred to.

By virtue of the above diagram we can derive various quantities as the functions of l. The result is summarized in Table I for positive and negative streamers whose velocities are 8×10^7 and 4×10^7 cm/s respectively.

§ 11. Stepped Leader of Lightning

According to the above table we can evaluate the step period $\varDelta\tau$ and step length $\varDelta l$ of a lightning leader if we put an appropriate l value in those expressions of a negative streamer; that is, for $l=3.0$ km* we get

$$\varDelta\tau=53.4\ \mu\text{s} \quad \text{and} \quad \varDelta l=21.4\ \text{m}.$$

These values show good coincidence with Schonland's data:

$$\varDelta\tau=50\ \mu\text{s} \quad \text{and} \quad \varDelta l=20\ \text{m}.$$

As to the positive lightning leader, the author knows only the data obtained at Empire State Building in New York. According to Hagenguth and Anderson's report[7], regular stepping with 25 μs period began to appear when a positive leader advanced 300 ft high above the building and continued up to 500 ft. The velocity was 3×10^7 cm/s.

Table I. Summary of Calculation Formulas
(Unbroken length l in cm)

Quantity	Negative Streamer ($v_0=4\times10^7$ cm/s)	positive Streamer ($v_0=8\times10^7$ cm/s)
spark voltage V (kV)	$5l$	$5l$
charge/length q (coul/cm)	$3.2\times10^{-11}l$	$3.2\times10^{-11}l$
tip field X_0 (kV/cm)	230	660
pilot radius r (cm)	$3.34\times10^{-3}l$	$1.13\times10^{-3}l$
channel radius R (cm)	$4.27\times10^{-3}l$	$4.27\times10^{-3}l$ ($\rho_1=2.5\times10^{-3}l$)
streamer current I (A)	$1.28\times10^{-3}l$	$2.56\times10^{-3}l$
channel current density J (A/cm²)	$22.4/l$	$44.8/l$ ($130/l$)
channel internal field E_R (kV/cm)	3.0	3.0
channel electron density N_R (cm⁻³)	$1.11\times10^{14}/l$	$2.22\times10^{14}/l$ ($6.43\times10^{14}/l$)
step period $\varDelta\tau$ (μs)	$1.78\times10^{-4}l$	$\varDelta\tau_1=3.86\times10^{-5}l$ $\varDelta\tau_2=0.138l$
step length $\varDelta l$ (cm)	$7.12\times10^{-3}l$	$\varDelta l_1=3.08\times10^{-4}l$ $\varDelta l_2=11l$

(Parenthesized values of the last column are for ρ_1.)

The position 300 ft above the building corresponds to 480 m above the earth surface. If we assume the negative cloud as 3.5 km high above the earth, l between the leader tip and cloud amounts 3 km long. Inserting this l-value into $\varDelta\tau_1$-expression, we get

$$\varDelta\tau_1=26.5\ \mu\text{s},$$

which is quite satisfactory provided that the $\varDelta\tau_1$-formula of Table I is corrected to the measured v_0.

§ 12. Streamers of Ordinary Gaps

Table I tells us that for 1 m gap length the radius of channel is equal to 0.427 cm and it decreases with its advance toward the opposite plane electrode. The current is several tenths of ampere and the current density reaches hundreds mA/cm^2.

---

* This implies a streamer which has spreaded 500 m long from the negative cloud 3.5 km above the earth surface.

The radius of the channel is equal for positive and negative streamers, but we have already noticed that the positive streamer has a tendency to take the semifinal radius ρ_1 determined by ionization limit, which becomes 0.25 cm for $l=1$ m. Therefore the positive steamer radius is equal to or rather less than the negative one, that seems quite cooperative with our understanding about streamers.

As to the stepping of ordinary gap streamers the thory suggests following remarks.

For negative streamers the step period becomes hundredth of microsecond, which can hardly be observed by a rotating camera.

For positive streamers, the step period becomes several microseconds if $\Delta\tau_2$ determines it and therefore observable. However as the step length Δl_2 becomes almost equal to or rather larger than the electrode distance, it may be hard to observe regularly stepped streamers.

§ 13. Temperature Rise of Streamer

We have so far left this problem untouched, but here we show that no sensible rise of temperature can occur in any streamer.

The energy input W per 1 g of air at any part of the streamer is given by the following expression:

$$W=J_R E_R \tau \frac{n_1}{N}, \tag{38}$$

where τ is the duration of that portion up to spark occurrence and given by l/v_0, n_1 the number of gas molecules per 1 g of air and N that per unit volume.

A part of this energy is lost by thermal conduction and radiation, but we leave these losses out of consideration for a while and assume that the total energy is spent exclusively on raising the streamer temperature. Then the final temperature rise ΔT is given by W/c_p, where c_p is the specific heat of air under constant pressure. Since

$$n_1=2.08\times10^{22}, \quad N=2.7\times10^{19},$$

$$c_p=0.24 \text{ cal/g deg} \quad \text{and} \quad E_R=3.0 \text{ kV/cm},$$

we get

$$\Delta T=1.4 \text{ deg}. \tag{39}$$

Even the optimum value is thus extremely small. Actual ΔT must be smaller than this limit value and so we need not consider the temperature effect at all. We can therefore safely conclude that streamers can not have arc property by itself so far as our theory is not wrong.

The above temperature rise occurs uniformly along the streamer and also is independent of v_0 and polarity of the streamer.

§ 14. Remarks

A) We determined the channel radius R from the self-maintaining condition (10) for electrons. Outside the surface of R-cylinder electrons are estimated to be able to move only $3\sim4$ cm along the field before they attach upon gas molecules. Owing to this reason there must exist an ion-layer immediately outside the channel. The charge q which is required to protect the plasma from the external field is due to the difference between positive and negative ions per unit length of this layer. The densities of positive and negative ions in this layer are calculated to be of the order of $10^{14}/l$, provided that the layer thickness is assumed to be $10^{-3}\,l$.

B) The proof that the condition (10) also exists in the channel may be given as follows. If we consider the balance of loss and generation of electrons in volume element $2\pi\rho d\rho$ around the axis the following equation is obtained:

$$-D_a\frac{dN}{d\rho}2\pi\rho+D_a\frac{d}{d\rho}\left(N+\frac{dN}{d\rho}d\rho\right)2\pi(\rho+d\rho)$$
$$+Z_G N d\rho 2\pi\rho-\beta N d\rho 2\pi\rho=0,$$

where N is electron density, D_a ambipolar diffusion coefficient and Z_G, β the same as in § 5.

Putting

$$x=\rho\sqrt{\frac{Z_G-\beta}{D_a}},$$

the above equation is transformed into the form

$$\frac{d^2N}{dx^2}+\frac{1}{x}\frac{dN}{dx}+N=0,$$

therefore

$$N=J_0(x).$$

If we assume that $N=0$ at $\rho=R$ as in the theory of positive column of glow discharge,

$$Z_C-\beta=D_a\left(\frac{2.45}{R}\right)^2 .$$

Inserting the known values of R and D_a (=1.16 for E_R)

$$Z_C-\beta=\frac{3.83\times10^5}{l^2} .$$

Since Z_C and β are of the order of 10^6 as shown in Fig. 2, we get

$$Z_C-\beta\sim0 ,$$

that is, the same result as (10).

C) As to the pilot model applied in this theory, there still remains a doubt about its appropriateness. To avoid an unconceivably large value of stem capacity, the author assumed that the head-sphere is electrically insulated from the stem as explained in § 3.

However this assumption causes another difficulty that the potential difference between the stem and the head-sphere $(Kl-X_0r)$ takes unreasonably large value. This is quite the question left for future study.

About the model of head-sphere structure we may probably suggest that the head-sphere has some intimate relation to the phenomenon " ball-lightning " as it is called, whose structure remains still mysterious. When a lightning leader runs athwart the vertical field of thunder-storm, under-voltage state will appear at the leader tip (refer to § 5), and the freshly producing stem part will not be able to maintain enough potential difference against the head-sphere and thus has a liability to let it free. The origin of the ball-lightning may then be explained by such a detached head-sphere.

Acknowledgement

The author wishes to express his cordial thanks to the research group on gaseous discharge in his laboratory and also to the members of lightning study in Meteorological Laboratory for their helpful discussions. His appreciation is also due to the financial aid granted by the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 12, DECEMBER, 1957

On a Theory of Shock Waves in Locally Supersonic Zone and a New Boundary-value Problem for Tricomi's Equation

By Shun-ichi TSUGÉ

Department of Aeronautics, Faculty of Engineering, University of Tokyo, Tokyo

(Received September 5, 1957)

The hodograph behavior of the shock wave in transonic flow with non-uniform initial state is discussed. Besides the shock polar, two conditions are derived which, as a special case, comprise Busemann's spine and serve to eliminate the indeterminateness which constitutes specific difficulty for the treatment of high subsonic flow with shock waves. Applying these three equations to the transonic flow over an airfoil, a new boundary-value problem is proposed. The problem still involves indeterminateness, but in a special case when the airfoil has a ridge it can be simplified so as to develop further analysis.

§ 1. Introduction

The early stage of the investigation of the transonic flow was exclusively confined to the discovery of the possibility of smooth deceleration through the speed of sound. Though the contributions of S. Tomotika & K. Tamada1), M. J. Lighthill2) and T. M. Cherry3) gave the affirmative conclusion for this problem, the real phenomena or the results of experiments could hardly be in accord with these theoretical predictions. Thus the second stage to be proposed for the theory of transonic flow should be to revise the existing theory so as to allow the occurrence of shock waves. In this case, however, there occurs a mathematical indeterminateness (in the hodograph plane); one shock polar is not sufficient as in the treatment of the detached shocks and a *series* of them are necessary whose initial state distributes along a curve which itself is unknown. Thus we encounter with the boundary-value problem in which neither the boundary nor the boundary condition is prescribed. Though it seems impossible at the present stage to find out all of the lacking conditions, it is found that some of them can be derived as an immediate result of the shock relation, which in a special case has led A. Busemann4) to the discovery of the "spine". We shall show how these relations are found out and we shall also give some criticism for their ability to construct complete flow pictures.

§ 2. The Fundamental Equations

Since whole procedure is carried out in the hodograph plane, we must, from the outset, assume the two-dimensional character of the flow problem. Furthermore, the neglect of the vorticity induced by the presence of the shock should be postulated. This approximation seems doubly beneficial, since the main object of the present investigation, i.e. non-uniform state before the shock, is a phenomenon only proper to the transonic flow ($M \lesssim 1$). This is accomplished by assuming the flow to be in the transonic range:

$$q=a^*\{1+(\gamma+1)^{-1/3}w\}\ , \qquad w \ll 1 \qquad (1)$$

where q is the magnitude of the velocity vector, a^* critical speed of sound and γ the adiabatic index (=1.4 for air).

Under the assumption (1) the gasdynamic equation is simplified to the degree that it gives the well-known Tricomi's equation:

$$\Psi_{ww}-w\Psi_{\theta\theta}=0\ , \qquad (2)$$

where Ψ is the stream function and θ is the inclination of the velocity vector measured counterclockwise from the direction of undisturbed stream. In supersonic region ($w>0$) Eq. (2) is associated with the family of characteristic curves:

$$d\theta/dw=\pm w^{1/2} \text{ or } \theta\mp(2/3)w^{3/2}=\text{const.} \qquad (3)$$

In gasdynamics the boundary conditions are made up of two factors, namely, the condition on the surface of the obstacle and the condition on the shock wave. If we lay aside the details concerning the first, the second condition is expressed as follows:

$$\theta-\tilde{\theta}=\pm(\tilde{w}-w)\sqrt{(w+\tilde{w})}/2\ , \qquad (4)$$

and

$$dy/dx=(\gamma+1)^{-1/3}(\tilde{w}-w)/(\theta-\tilde{\theta})\ , \qquad (5)$$

where the quantities with and without the tilde (~) refer respectively to those measured immediately before and after the shock wave. Eq. (4) which is the equation for shock polar to transonic approximation shows the locus of the possible shock transition from any point in supersonic domain of the hodograph plane, and Eq. (5) gives the direction of the shock wave in the physical plane. These are the immediate consequences of the rotation of the axis of reference of the ordinary shock relations ($\tilde{\theta}=0$), but we should remark that this rotation brings essential feature of non-uniformity before shocks in which we are interested.

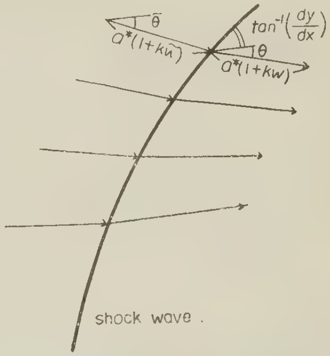

Fig. 1. Shock wave with non-uniform initial state ($k=(\gamma+1)^{-1/3}$).

§ 3. Relation between the Limiting Line and the Shock Wave

In 1941, von Kármán5) predicted that the location of the shock wave on the airfoil with embedded supersonic zone concides with the line of break-down of the mapping from the hodograph to the physical plane. Analytically

$$\partial(x, y)/\partial(q, \theta)=0\ , \tag{6}$$

which, by use of the relations:

$$\left.\begin{aligned} x_w&=(\gamma+1)^{1/3}w\Psi_\theta\ ,\\ x_\theta&=(\gamma+1)^{1/3}\Psi_w\ ,\\ y_w&=\Psi_w\ ,\\ y_\theta&=\Psi_\theta\ , \end{aligned}\right\} \tag{7}$$

is written as:

$$\Psi_w^2-w\Psi_\theta^2=0\ , \tag{6a}$$

while, along the streamline, we have

$$0=d\Psi=\Psi_w dw+\Psi_\theta d\theta\ ,$$

or

$$(d\theta/dw)_\Psi=-\Psi_w/\Psi_\theta\ . \tag{8}$$

Then the condition (6a) results in

$$(d\theta/dw)_\Psi=\pm w^{1/2}\ , \tag{6b}$$

where the subscript Ψ denotes the differentiation along the streamline. The left-hand side of (6b) specifies the direction of the spine in Busemann's sense. By Eq. (3) this condition (6b) may be written in an alternative form:

$$(d\theta/dw)_\Psi=(d\theta/dw)_{\text{characteristic}}\ . \tag{6c}$$

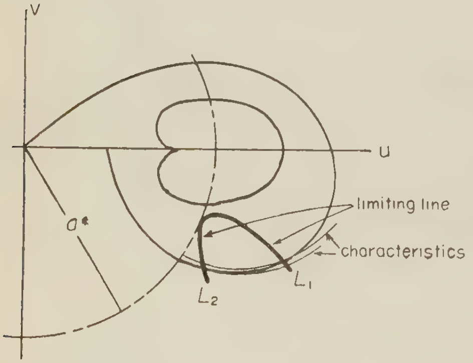

Fig. 2(a). Flow with a limiting line (hodograph plane).

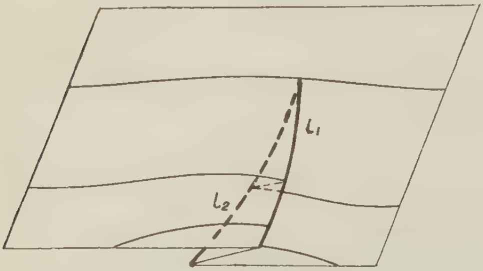

Fig. 2(b). Flow with a limiting line (physical plane).

This is an important property of the limiting line. Its conspicuous feature in the physical plane is the reflection of the streamline along it. Then, in general, the physical plane is composed of three sheets, which is physically impossible (Fig. 2b).

To correct the situation, we must give up the premise "irrotationality" or we must admit the presence of the shock wave between l_1 and l_2[6] (Fig. 3b). But if the physical plane is revised so as to be made up of a single sheet, the corresponding hodograph plane must have a *crevice* limited by S^+ and S^- between which L_1 and L_2 locate. Then the question arises: "How can the shock wave S^+ and S^- be predicted (in the hodograph plane)?" We cannot, however, content ourselves with

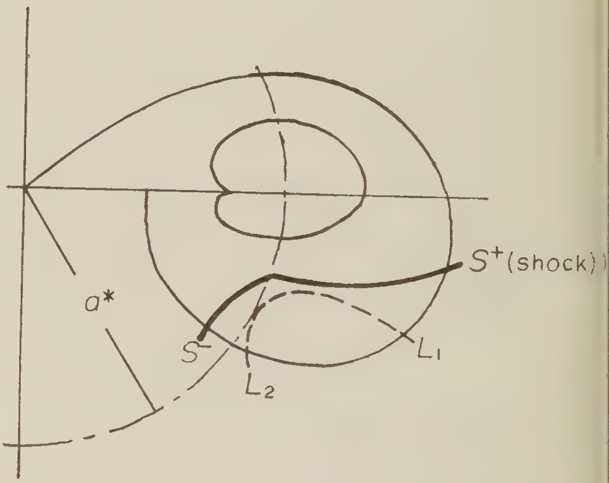

Fig. 3(a). Flow with a shock wave (hodograph plane).

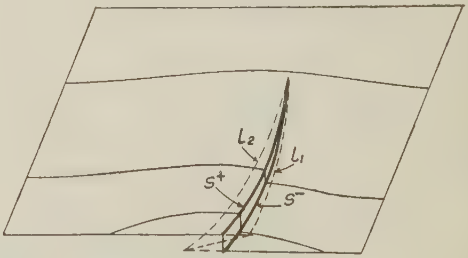

Fig. 3(b). Flow with a shock wave (physical plane).

knowing its shape only, but we have to inquire further after the boundary condition held along it. Then the second question asks "How is the specified condition on S^+ and S^- instead of the condition (6b) on L?" These two questions have to be discussed and to be answered in the following sections.

§ 4. Hodograph Behavior of the Shock Wave with Non-uniform Initial State

There is an asymmetry in the expression (5) of the shock wave, since the left-hand side involves the quantities of the physical plane, while the right-hand side is exclusively composed of the hodograph variables. We shall now express the left-hand side in terms of the hodograph variables. Differentiating x and y along the shock wave and making use of (7), we have

$$dx = x_w dw + x_\theta d\theta = (\gamma+1)^{1/3}(w\Psi_\theta dw + \Psi_w d\theta) ,$$

$$dy = y_w dw + y_\theta d\theta = \Psi_w dw + \Psi_\theta d\theta .$$

Then Eq. (5) becomes

$$\frac{(d\theta/dw)_S + \Psi_w/\Psi_\theta}{w + (\Psi_w/\Psi_\theta)(d\theta/dw)_S} = \frac{\tilde{w}-w}{\theta-\tilde{\theta}} ,$$

or, by Eq. (8),

$$\frac{(d\theta/dw)_S - (d\theta/dw)_\Psi}{w - (d\theta/dw)_S (d\theta/dw)_\Psi} = \frac{\tilde{w}-w}{\theta-\tilde{\theta}} , \tag{9}$$

where the subscript S denotes the derivative "along the shock wave", while Ψ denotes the derivative "along the streamline".

As we have seen in the preceding section, a single curves of the shock wave in the physical plane is splitted up into *two* branches S^+, S^- in the hodograph plane. Thus we must apply the condition (9) to each of them, and therefore *single equation* (5) *produces two conditions* of the following form:

$$\frac{(d\tilde{\theta}/d\tilde{w})_S - (d\tilde{\theta}/d\tilde{w})_\Psi}{\tilde{w} - (d\tilde{\theta}/d\tilde{w})_S (d\tilde{\theta}/d\tilde{w})_\Psi} = \frac{\tilde{w}-w}{\theta-\tilde{\theta}} \quad (\text{along } S^+) , \tag{10}$$

and

$$\frac{(d\theta/dw)_S - (d\theta/dw)_\Psi}{w - (d\theta/dw)_S (d\theta/dw)_\Psi} = \frac{\tilde{w}-w}{\theta-\tilde{\theta}} \quad (\text{along } S^-) . \tag{11}$$

These two equations, in conjunction with Eq. (4) give information about the flow just before and after the shock wave. It is of some interest to remark here that if we formally regard the tilde as the operator for producing the complex conjugate, the operation of it over Eq. (10) gives Eq. (11) and *visa versa*, while Eq. (4) remains unchanged. Thus the set of equations (4), (10) and (11) are *symmetrical* with respect to the quantities with and without the tilde (dynamical reversibility), and the only asymmetry arises from the second law of thermodynamics:

$$\tilde{w} > w .$$

In case when we deal with a flow with a head wave ($\tilde{w} = w_\infty =$ const. and $\tilde{\theta} = 0$) as a special case, the curve S^+ shrinks into a point. In such a case Eq. (10) proves to be meaningless and Eq. (11) together with Eq. (4) gives the shock polar and Busemann's spine.

§ 5. Correspondence between the Initial and Final State of Shock Transition

Let P$^+$ be a point just ahead of the shock wave in the velocity plane and P$^-$ the corresponding point after the shock transition. The terminology "corresponding" means that they have the same value for the stream function. In the case of non-uniform initial state, they have one-to-one correspondence, which we may denote

$$\tilde{w} = f(w) . \tag{12}$$

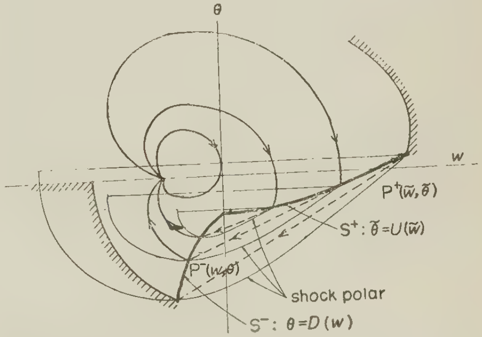

Fig. 4. Schematic figure in the vicinity of the shock wave.

Now we propose a problem: Given a initial curve:

$$S^+: \quad \tilde{\theta} = U(\tilde{w}) , \tag{13}$$

and the "spine" along it:

$$\tilde{\mu} = \tilde{\mu}(\tilde{w}) = (d\tilde{\theta}/d\tilde{w})_\Psi \tag{14}$$

what can be said about

1) the transforming function f,

2) the curve S^- of the final state $\theta = D(w)$, and

3) the spine towards downstream

$$\mu=\mu(w)=(d\theta/dw)_\Psi ?$$

The first question can immediately be answerd by Eqs. (4) and (10). Thus,

$$U'(f)\tilde{\mu}(f)\pm\sqrt{(w+f)/2}\{U'(f)-\tilde{\mu}(f)\}-f=0\,, \tag{15}$$

in which only $f(w)$ stands as the unkown. Once the transforming function $\tilde{w}=f(w)$ is found by the algebraic relation (15), the knowledge of the distribution of values of Ψ on S^+ can readily be shifted to that on S^- as stated at the beginning of this section. The function $f(w)$, thus specified, further contributes to answer the second question when we substitute it into Eq. (4),

$$\theta=D(w)=U(f)\pm(f-w)\sqrt{(w+f)/2}\,. \tag{16}$$

Finally the direction of the spine on S^- towards downstream is found from Eq. (11) by noticing Eqs. (15) and (16)

$$\mu(w)=\left(\frac{d\theta}{dw}\right)_\Psi=\frac{f\mp\sqrt{(w+f)/2}D'(w)}{D'(w)\mp\sqrt{(w+f)/2}}\,. \tag{17}$$

Thus Eqs. (15), (16) and (17) fix the physical state after the shock transition in terms of the initial state.

Hence, we must proceed to the second stage, viz. the state of affairs governing the initial state itself. Though the complete construction of the problem is the subject of the next section, it will be useful, as a stepping stone to go further, to remark the following fact. Though, as the matter of definition, the characteristic curve (Eq. (3)) is such that the discontinuity of the higher derivatives than the second order of the dependent variable can propagate along it, which, under some condition, can also be a carrier of the discontinuity of the first order derivative (shock wave!)[7]. So it stirs up our curiosity whether the curve S^+ coincides with one of the characteristic curves (plus family of Eq(3)) or not. If S^+ is a characteristic,

$$\tilde{\theta}=U(f)=\frac{2}{3}f^{3/2}\,.$$

When it is applied to Eq. (15), we have

$$(\sqrt{f}\mp\sqrt{(w+f)/2})(\tilde{\mu}(f)-\sqrt{f})=0$$

$$\text{i.e. } w=f \text{ or } \tilde{\mu}=f^{1/2}\,.$$

The demand for $w=f$ allows no discontinuity, so that it is reduced to an ordinary Mach wave. The second requirement $\tilde{\mu}=\sqrt{f}$ is identical with the limiting line condition (6). Thus we can summarize this fact as follows: Unless the limiting line is identified with a characteristic curve, the discontinuity due to the shock wave runs along a curve different from one of the characteristics. This fact, though seemingly trivial, brings inner importance when it provides us with a critical difference between Tricomi's problem and the one to be proposed in the next section.

In the same way, the possibility for the limiting line L_1 to coincide with the initial shock curve S^+ is discussed by the use of the limiting line condition (6b):

$$\tilde{\mu}(f)=f^{1/2}\,.$$

Substitution of it into Eq. (15) gives

$$(\sqrt{f}\pm\sqrt{(w+f)/2})(U'(f)-\sqrt{f})=0\,,$$

$$\text{i.e. } w=f \text{ or } U=\frac{2}{3}f^{3/2}\,.$$

Thus, the requirement is either that the transition is continuous, or that the initial line is a characteristic curve. Consequently, L must locate somewhere *between* S_1^+ and S_2^- (see again Fig. 3.a) since the extreme case is prohibited.

§ 6. A New Boundary-value Problem

Let us devote our attention to the state of affairs only about the initial curve of the shock wave S^+ (Fig. 5). By the preceding discussion the possibility that the initial curve S^+ coincides with a characteristic curve Γ_o is excluded. Furthermore, it can be generally concluded that S^+ lies inside the curvilinear triangle ACE. For, if the opposite situation stood, S^+ would be steeper than Γ_o, so that

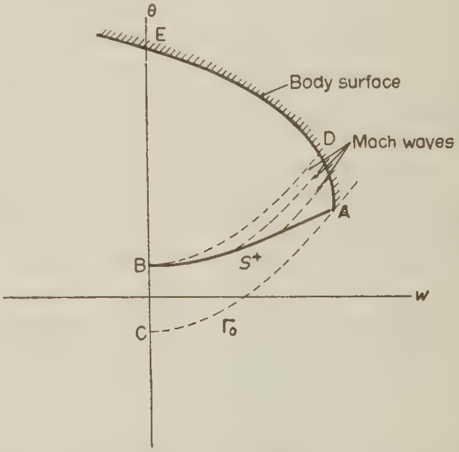

Fig. 5. Initial state of the shock wave and Mach waves from the body surface.

compression Mach wave originating from any part of the body surface could not reach it. This prediction is in accord with the experiment carried out by F. Tamaki[8] (Fig. 6).

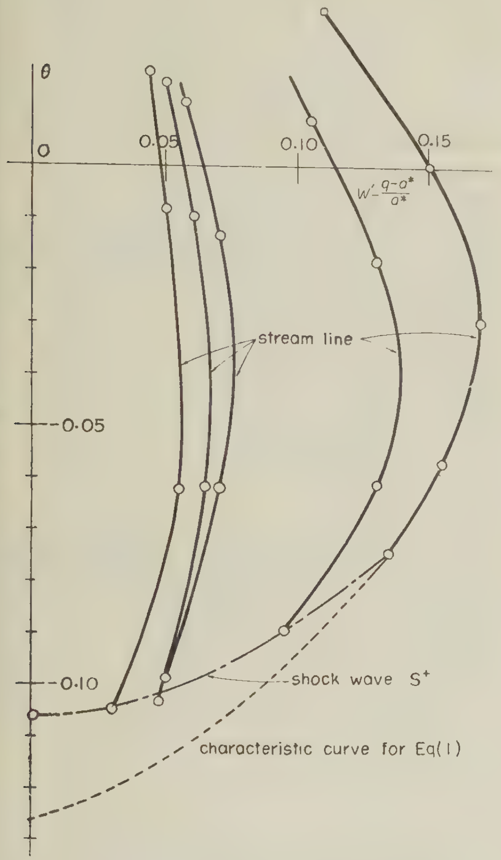

Fig. 6. Transonic flow over a Tomotika-Tamada airfoil at $M_\infty=0.763$ (Tamaki's experiment[8]).

Thus we come to the following problem: (New boundary-value problem) *Search for the solution of the equation*

$$\Psi_{ww}-w\Psi_{\theta\theta}=0\ ,$$

which satisfies the following boundary conditions: (see Fig. 7)

I. $\Psi=0$ on CDEA ,

where A *lies outside the curvilinear triangle* EFB, *where* EF *and* BF *are characteristic curves of the opposite family expressed by Eq. (3).*

II. *Along* S^+ (*or* AB) *and* S^- (*or* BC), *three conditions (15), (16) and (17) are prescribed.*

Our problem becomes much involved by the presence of the shaded part of Fig. 7 due to which the indeterminateness will occur in general. If the troublesome area vanishes, viz. if A situates on characteristic curve BF, we have Frankl's problem and as a special case if A is identified with F, our problem is reduced to Tricomi's one so long as one is concerned with the configuration in the hyperbolic domain. The second and no less important difference between the present and Tricomi's or Frankl's problem is the condition II, that is, the boundary value (according to Eq. (15)) and the derivatives (according to Eq. (17) and Eq. (8)) are prescribed *simultaneously* on S^-. Thus we encounter the overdetermined boundary-value problem in subsonic range, while, as we have seen, the supersonic domain involves underdetermination. In the present stage, we have no knowledge how to relate these under- and over-determinations, but we shall see that difficulties are reduced to some extent in the following special case.

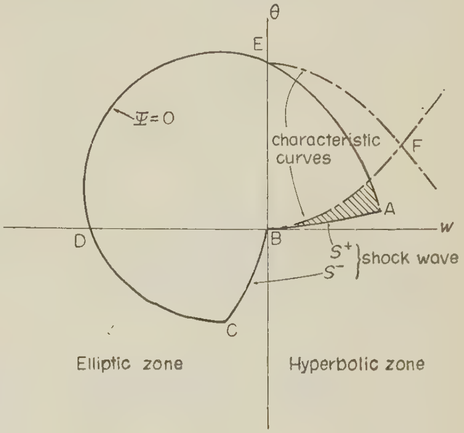

Fig. 7. New boundary-value problem.

§ 7. Flow round a Finite Wedge

In order to allow a simple hodograph configuration, let us choose, as a special model, a finite wedge immersed in gas flow, the free-stream Mach number of which is not much less than unity (Fig. 8). This problem was already solved by J. D. Cole[9] in the form of a singular (fundamental) solution which satisfies the boundary condition along CD and DE and is *opened free* for the remaining parts of the boundary. The exact setup of the problem on the standpoint of the present theory is shown in Fig. 8. viz.

I. $\Psi=0$ for $\theta=0,\ \theta=\theta_0$ $(w<0)$,

$\theta+(2/3)w^{3/2}=\theta_0$ $(w>0)$, where θ_0 is the half-wedge angle,

II. Along S^- the following two conditions are prescribed:

$$U'(f)\tilde{\mu}(f) \pm \sqrt{(w+f)/2}\{U'(f)-\tilde{\mu}(f)\}-f=0\,, \tag{15}$$

where, as before,

$$\tilde{w}=f(w)\,,$$

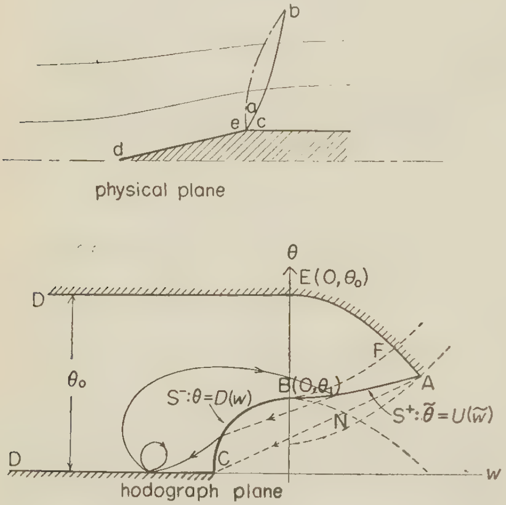

Fig. 8. Transonic flow round a wedge.

and

$$\mu(w)=\frac{f \mp D'(w)\sqrt{(w+f)/2}}{D'(w) \mp \sqrt{(w+f)/2}}\,. \tag{17}$$

III. S^- is specified by

$$\theta=D(w)=U(f) \pm (f-w)\sqrt{(f+w)/2}\,. \tag{16}$$

We should remark here that $U(f)$, or the curve AB is not given by the initial data, but belongs to *some* curve connecting the sonic line and the characteristic curve originating from E. So is also the curve BC or $D(w)$, since it depends on the behavior of $U(f)$ by Eq. (16) (Boundary-value problem with floating boundary curve).

But the present flow problem includes a special profit, viz. the coincidence of the boundary EA with a characteristic curve (Prandtl-Meyer expansion wave), which allows a remarkable simplification. For, then, the area ABF can be determined unlike the general problem stated in the preceding section. This can be verified by use of the special technique of analysis known as *the characteristic initial-value problem* in the following way.

As stated before, we are to treat Tricomi's problem if we replace the curvilinear triangle EBA by EBF in the configuration in hyperbolic domain. Then through the use of the initial data on the sonic line EB

$$\left.\begin{aligned}\Psi(0,\theta)&=\tau(\theta)\,,\\ \Psi_w(0,\theta)&=\nu(\theta)\,,\end{aligned}\right\}\quad \text{for} \quad \theta_1 \leqq \theta \leqq \theta_0 \text{ or EB}$$

Cauchy's problem is solved inside EBF[10]:

$$\begin{aligned}\Psi(w,\theta)=&-\frac{\Gamma(5/3)}{\{\Gamma(5/6)\}^2}\,w\int_0^1 \nu\left(\theta+\frac{2}{3}w^{3/2}(2t-1)\right)t^{-1/6}(1-t)^{-1/6}dt\\ &+\frac{\Gamma(1/3)}{\{\Gamma(1/6)\}^2}\int_0^1 \tau\left(\theta+\frac{2}{3}w^{3/2}(2t-1)\right)t^{-5/6}(1-t)^{-5/6}dt\,.\end{aligned} \tag{20}$$

Then we have the boundary value on BF,

$$\begin{aligned}\Psi=G(w_s,\theta_s)=&-\frac{\Gamma(5/3)}{\{\Gamma(5/6)\}^2}\,w_s\int_0^1 \nu\left(\theta_1+\frac{4}{3}w_s^{3/2}(t-1)\right)t^{-1/6}(1-t)^{-1/6}dt\\ &+\frac{\Gamma(1/3)}{\{\Gamma(5/6)\}^2}\int_0^1 \tau\left(\theta_1+\frac{4}{3}w_s^{3/2}(t-1)\right)t^{-5/6}(1-t)^{-5/6}dt\,.\end{aligned} \tag{21}$$

Since BF and FA are characteristics, only the value of Ψ (and not that of its derivatives) on BF and FA is necessary and *sufficient* for our purpose of determining the flow field FANB. We meet just the corresponding situation, viz.

$$\left.\begin{aligned}&\Psi=0 &&\text{on FA}\,,\\ &\text{Eq. (21)} &&\text{on BF}\,.\end{aligned}\right\} \tag{22}$$

It is not difficult to obtain the explicit expression for Ψ, since we have known Riemann's function for Tricomi's equation[10];

$$\left.\begin{aligned} &Z(\xi,\eta;\xi_s,\eta_s)\\ &\quad=\frac{(\xi-\eta)^{1/3}}{(\eta-\xi_s)^{1/6}(\eta_s-\xi)^{1/6}}F\left(\frac{1}{6},\frac{1}{6};1;\sigma\right),\\ &\text{and}\\ &\sigma=\frac{(\xi-\xi_s)(\eta_s-\eta)}{(\eta_s-\xi)(\eta-\xi_s)},\end{aligned}\right\} \tag{23}$$

where ξ, η are the characteristic coordinates of Eq. (1),

$$\left.\begin{aligned}\xi&=\theta-(2/3)w^{3/2},\\ \eta&=\theta+(2/3)w^{3/2}.\end{aligned}\right\} \tag{24}$$

Using Z thus defined, we have the complete solution valid inside the rectangle BNAF (Fig. 9)[11],

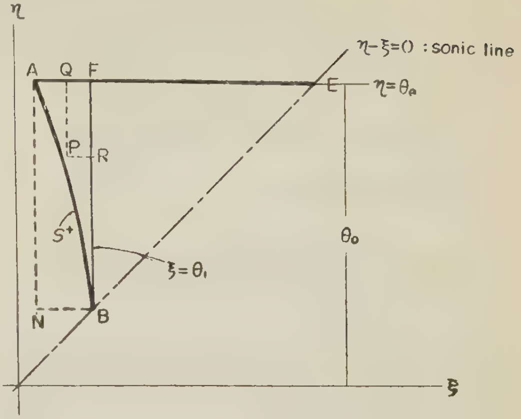

Fig. 9. Characteristic initial value problem.

$$\begin{aligned}(\Psi(\xi,\eta))_P&=(\Psi Z)_F+\int_F^R\left(\frac{\partial\Psi}{\partial\eta_s}-\frac{\Psi}{6(\theta_1-\eta_s)}\right)Zd\eta_s+\int_F^Q\left(\frac{\partial\Psi}{\partial\xi_s}+\frac{\Psi}{6(\xi_s-\theta_0)}\right)Zd\xi_s\\ &=(\Psi Z)_R-\int_F^R\left(\frac{Z}{6(\theta_1-\eta_s)}+\frac{\partial Z}{\partial\eta_s}\right)\Psi d\eta_s,\end{aligned} \tag{25}$$

by taking the condition (22) into consideration. This can be calculated by Eqs. (21), (22) and (23) to give a more intimate form

$$\Psi(\xi,\eta)=G(\theta_1,\eta)\frac{(\eta-\xi)^{1/6}}{(\theta_1-\eta)^{1/6}}-\int_{\theta_0}^{\eta}A(\xi,\eta;\theta_1,\eta_s)G(\theta_1,\eta_s)d\eta_s,$$

where

$$\begin{aligned}A(\xi,\eta;\xi_s,\eta_s)=\frac{1}{36}\frac{(\xi-\eta)^{1/3}}{(\eta-\xi_s)^{1/6}(\eta_s-\xi)^{1/6}}&\left\{6\left[\frac{1}{\xi_s-\eta_s}+\frac{1}{\xi-\eta_s}\right]F\left(\frac{1}{6},\frac{1}{6};1;\sigma\right)\right.\\ &\left.+\frac{(\xi-\xi_s)(\eta-\xi)}{(\eta-\xi_s)(\eta_s-\xi)^2}F\left(\frac{7}{6},\frac{7}{6};2;\sigma\right)\right\}.\end{aligned} \tag{26}$$

Thus the physical state is determined. Provided that the initial curve S^+: $\tilde{\theta}=U(\tilde{w})$ is assumed to be given, we can find the value of the spine

$$\tilde{\mu}(\tilde{w})=-\left(\frac{\Psi_w}{\Psi_\theta}\right)_{\substack{\theta=\tilde{\theta}\\ w=\tilde{w}}}=\tilde{w}^{1/2}\cdot\frac{\Psi_{\tilde{\xi}}-\Psi_{\tilde{\eta}}}{\Psi_{\tilde{\xi}}+\Psi_{\tilde{\eta}}},$$

the right-hand side of which being calculated by Eq. (26).

Summarizing, in virtue of the reduction to the characteristic initial-value problem, we have reduced the number of unknowns to a single quantity i.e. the shape of the initial state of the shock or S^+: $\tilde{\theta}=U(\tilde{w})$. How this unknown is connected with the compatibility of the simultaneous conditions (Eqs. (16) and (17)) on the final curve S^- is still too involved to allow a straightfoward analysis. Further investigation would be necessary to meet the complete physical pictures.

Phosphorescence of Acetic Acid

By Kikusaburo Osada

Faculty of Engineering, Nagoya University

(Received September 19, 1957)

It was reported in the previous paper¹⁾ that sodium- and potassium-acetates phosphoresce emitting a green light, when excited in vacuum with the ultraviolet radiation. In order to investigated the mechanism of this phenomenon, experiments on acetic acid were carried out at low temperatures.

Acetic acid (commercial reagent of the special grade) does not phosphoresce, when it is cooled near to −60°C with the mixture of dry ice and amyl acetate in apparatus as shown in Fig. 1 and is excited with the radiation. However, acetic acid solutions which are dissolved a little amount of $Na(C_2H_3O_2)$, KCl, or $NaHCO_3$, phosphoresce weakly emitting a green light at lower temperature than −30°C. We measured the decay curves of afterglow of them at several temperatures between −30°C and −60°C by a photo-multiplier tube with a d.c. amplifier and an oscilloscope¹⁾, and estimated the initial intensity by the extrapolation of the curve. The relations between the intensity and temperature are shown in Fig. 2. It was observed by using the two filters (Matsuda V–C1B and V–Y1A) that these spectra composed of a green band and a blue one, but the intensity of them was too weak to record separately the decay curve of each band. When lead acetate is used as solute, we can not observe the emission down to −60°C.

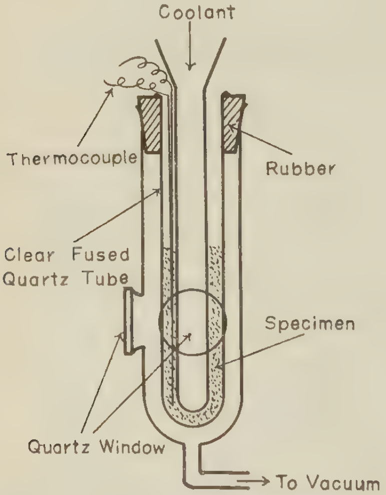

Fig. 1. Apparatus for observation of phosphorescence.

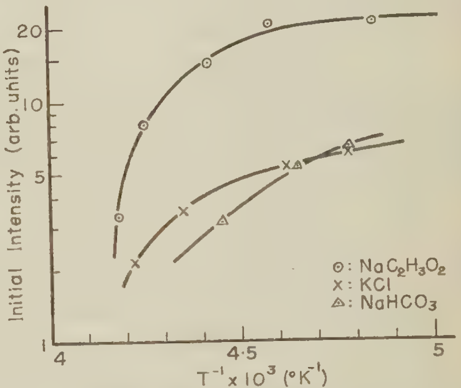

Fig. 2. Temperature dependence of phosphorescence of acetic acid contained a salt.

Here, we shall consider the origin of phosphorescence from these results. When the acetic acid solutions are cooled down, they solidify at lower temperature than that of melting point of acetic acid. We can not measure the state and amount of salts which are contained in the solidified acetic acid, but the salts seem to be slightly contained in ionic state as impurities in the solid. The salts do not phosphoresce by themselves with the exception of sodium- and potassium-acetates, after excited in vacuum with the ultraviolet radiation, and acetic acid contained lead acetate does not, too. Therefore, we may conclude that the phosphorescence is due to sodium- and potassium-ions which are contained as impurities in the solidified acetic acid and interact with the acetic ions.

Experiments on the Cylindrical Blast Waves

By Kōichi ŌSHIMA

Institute of Science and Technology, University of Tokyo, Tokyo

(Received November 11, 1957)

Since a century ago, a number of investigators[1] have studied the phenomena of electrically "exploding wires" observed when a bank of large capacitors is discharged through a very fine wire. The author observed the internal structure, the propagation and the reflection of disturbance waves produced by these explosions in the surrounding medium.

The mild copper wires with diameters ranging from 0.1 to 0.16 millimeter were stretched perpendicularly to two parallel flat walls 5 centimeter apart, and exploded by the discharge current of condensers with capacity of 2–10 microfarads charged by 4–10 kilovolts source. The disturbances created by this method were observed through the glass windows attached on the walls using the instantaneous photographs of schlieren method and Mach-Zehnder interferometer. These disturbances are typical cylindrical blast waves preceded by a shock wave. The two-dimensional character of the blast wave was verified by the photographs taken parallel to the two walls.

The ratio of the air density inside the blast wave, ρ, to the one of the outer still air, ρ_0, are presented in Fig. 1, where D is the diameter of the exploded wire, C is the capacity of the condenser bank, V is the charging voltage, r is the distance from the exploded wire and R is the distance from the wire to the shock front. These curves were measured from the interferograms taken at 250 microseconds after the explosion, and agreed qualitatively with the theoretical predictions.[2] By these curves and shock relations, the strength of the shock wave, p/p_0, was calculated and plotted in Fig. 2. As the charging voltage increases or the diameter of the wire increases, the shock wave becomes stronger. At the very low charging voltage, however, the explosion of the thick wire becomes incomplete.

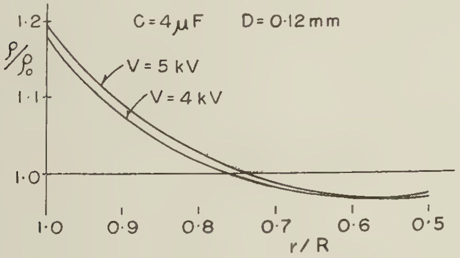

Fig. 1. Density Distribution.

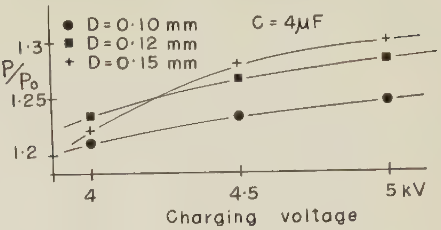

Fig. 2. Shock Strength.

Figs. 3 and 4 show the interferograms of the Mach and regular reflections of the cylindrical blast waves produced by this method on the flat surface. These interferograms were taken by the zero fringe method, so that the fringes appearing in the fields are the contours of constant density in the air. The so-called slip flow in the case of Mach reflection cannot be recognized on the interferograms, and the transition angle from regular to Mach reflection is greater than the one in the case of plane uniform shock wave with the same strength.

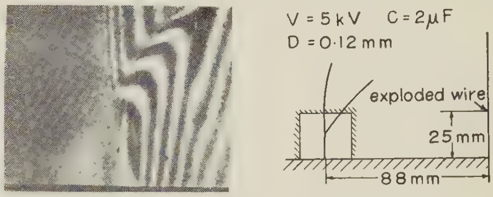

Fig. 3. Mach Reflection.

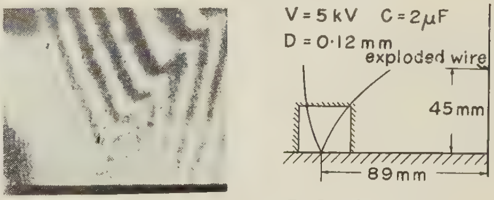

Fig. 4. Regular Reflection.

Similar experiments were carried out in water. The Mach and the regular reflection on the flat plate and the reflection on the free surface of the water were observed on schlieren photographs.

These experiments were carried out at the Institute of Science and Technology. The author wishes to express his sincere thanks to the members of the Institute for their encouragements and useful advice.

Effect of Electron Bombardment on Sodium Chloride

By Shigetomo YOSHIDA and Toshio IKEDA

Research Institute for Scientific Measurements, Tôhoku University, Sendai

(Received Septemper 12, 1957)

We have hitherto investigated the effect of electron bombardment on sodium chloride by electrical and optical methods.[1] This note concerns the formation of colloidal sodium in sodium chloride by electron bombardment.

Sodium chloride single crystals (5×5×1 mm) cleaved out from rock salt (Halle Co., Germany) were used as specimens after annealing. The bombarding voltage employed ranged from 7 to 20 KV while the current density and bombarding time were fixed at 40 μA/cm² and 60 minutes, respectively. The specimens were colored yellowish for the bombarding voltage below 13 KV and their absorption spectra showed distinct F and M absorption bands. At the voltage higher than 16 KV, blue-colored parts developed apperciably among yellowish ones. Under 20 KV bombardment the specimens acquired deep blue color. In the last case the strong absorption band with a peak at about 590 mμ was always accompanied by the weak one at 390 mμ, as shown in Fig. 1(a).

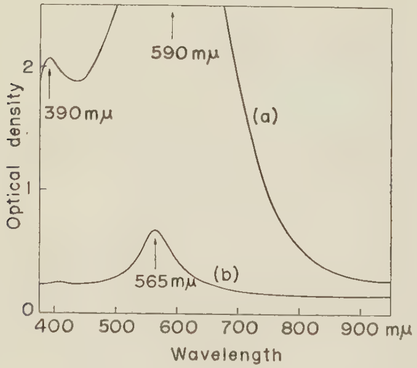

Fig. 1.

The same phenomenon was observed at 13 KV with the increase of current density from 40 μA/cm² to 70 μA/cm². When the specimens were kept at 150°C during bombardment, they also became blue in color even at the bombarding condition of 7 KV and 40 μA/cm².

Although this blue color was very stable at room temperature, the position of peak shifted to shorter wavelength side by annealing and reached to 565 mμ after the heating to 390°C at the rate of 0.7°C per minute, as shown in Fig. 1(b). This band, however, bleached entirely at 450°C and any other band was not observed at all.

On the other hand, when the specimens were maintained at high temperatures during bombardment, the position of peak shifted to longer wavelength side and the shape of band became less sharp. One example of this effect is shown in Fig. 2. Finally at about 300°C the specimens did not show any coloration and became cloudy.

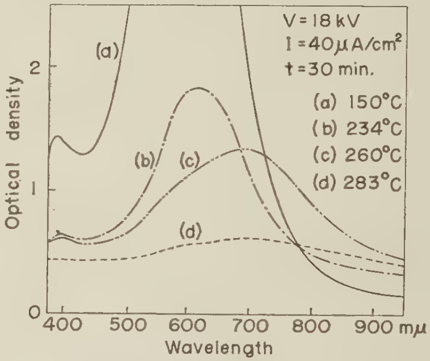

Fig. 2.

With specimens kept at high temperatures during bombardment, we observed also the scattering of dull red light from the crystal surface. This behaviour will be related to the scattering of light by colloidal particles, because their diameter, according to Savostianova's observation on natural blue rock salt, decides the position of peak of the absorption band and the rate of scattering. Thus, the strong absorption band with a peak at 590 mμ or thereabout may be identified as the colloidal band. Moreover, the before-mentioned weak peak at about 390 mμ may correspond to the peak of the photoconducing current curve plotted against the wavelength in blue or violet rock salt containing colloidal sodium[3].

From these results it may be concluded that the formation of colloidal sodium under electron bombardment is influenced greatly by the temperature of specimens which is also related to the bombarding wattage.

We are indebted to Prof. T. Hibi for the stimulating discussions and to the Electrical Communication Laboratory for the grant-in-aid.

Electrical Properties of SnTe, SnSe and InBi at Low Temperatures

By Kimio Hashimoto

Department of Physics, Faculty of Science, Kyusyu University, Hukuoka

(Received September 30, 1957)

The electrical resistivity ρ and the Hall coefficient R of SnTe, SnSe and InBi have been measured in the temperature range between about 2° and 100°K.

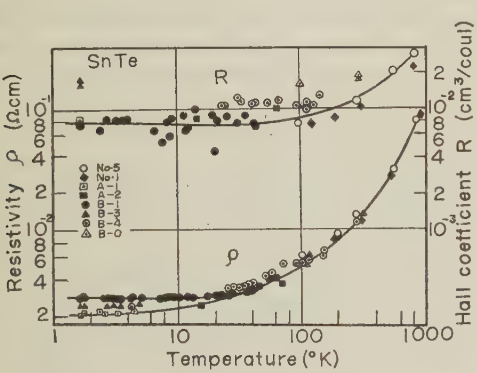

Fig. 1. Resistivity and Hall coefficient of SnTe as functions of temperature.

a) *SnTe.* R and ρ are shown in Fig. 1 as functions of the temperature. Both R and ρ increase with increasing temperature in the higher temperature range, but in the range below 30°K they seem to be independent of the temperature. The electrical properties of specimens No. 1 and No. 5 above liquid air temperature were reported in the previous letter.[1] A detailed discussion for the electrical properties of SnTe will be done elsewhere.

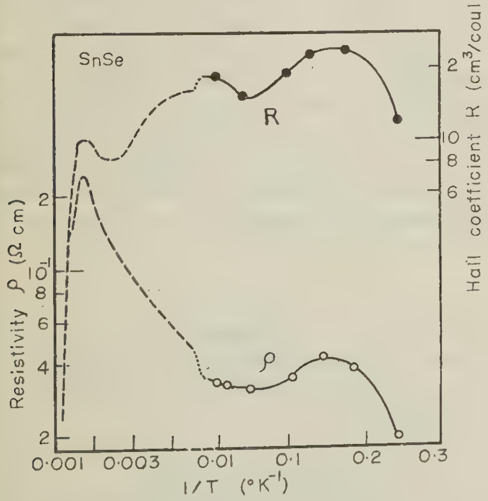

Fig. 2. Resistivity and Hall coefficient of SnSe as functions of temperature. Dotted curves show the values obtained by A. Okazaki and S. Asanabe[3].

b) *SnSe.* The temperature dependencies of R and ρ are shown in Fig. 2. Both R and ρ reach maximum values at about 6°K and then decrease with decreasing temperature.

c) *InBi.* The measured samples were the single crystal specimens used by S. Asanabe[2] for the investigation of anisotropy in resistivity above 100°K. The temperature dependency of ρ_{11}, the component of resistivity tensor, for specimen 503 is shown in Fig. 3 (see reference 2 for the definition of ρ_{11}). The linearity in the curve of ρ_{11} *versus* temperature is still maintained down to liquid helium temperature (see Fig. 2 in reference 2), but ρ_{11} decreases rapidly below liquid helium temperature. The Hall coefficient of specimen 503 could not be measured in the low temperature range. The transversal magnetoresistance effect of about 2% was observed for specimen 505A in the magnetic field of 20 000 Oe.

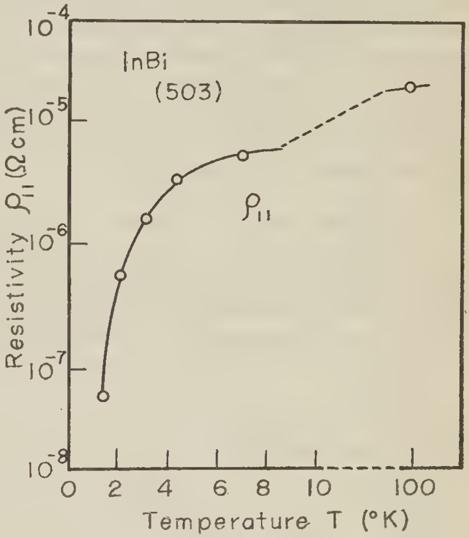

Fig. 3. Resistivity of InBi as a function of temperature.

I should like to express my hearty thanks to Professor T. Fukuroi, Professor Y. Shibuya and Professor S. Tanuma of the Research Institute for Iron, Steel and Other Metals, Tohoku University, for their guidance and for placing research facilities at my disposal.

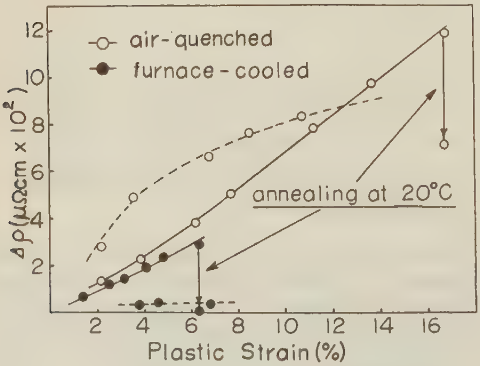
On the Formation of Small Guinier-Preston (1) Aggregates During the Plastic Deformation of an Al-Cu Alloy

Keisuke MATSUURA
Hokkaido Gakugei Univ.
Yoshikazu HAMAGUCHI*
and
Shigeyasu KODA
Hokkaido Univ.

(Received September 9, 1957)

As previously reported[1], an abnormal increase of the electrical resistivity was observed during the plastic deformation of a supersaturated solid solution of an Al-Cu 4% alloy in room temperature, but the increase was of an ordinary order in an alloy of over-aged state. This abnormal increase of the supersaturated solid solution may be associated with the formation of small Guinier-Preston (1) aggregates that occurs during the plastic deformation. This interpretation presented by the authors is consistent with the results of X-ray investigation by Graf and Guinier[2] and of the tensile testing of single crystals by Carlsen and Honeycombe[3]. In this short note, a fuather information of such an abnormal change of the electriclal resistivity during the plastic deformation will be given.

Polycrystalline wires of 0.95 mm. in diameter were solution-treated for 30 minutes at 530°C. One group of them was air-quenched in order to obtain a state of supersaturated solid solution and the other was furnace-cooled so that a state of over-ageing was attained. The resistivity of these specimens was measured during the deformation of pure extension in room temperature and at −196°C, respectively.



---- deformed at room temperature.
—— 〃 at −196°C.

Fig. 1. Increaces in specific resistivity by the plastic deformation.

The figure shows a typical example of the results. In an air-quenched specimen, the magnitude of resistivity change $\Delta\rho$ at room temperature showed a remarkably rapid increase in the range of small plastic strain ε. So, the $\Delta\rho-\varepsilon$ curve is convex. However, the resistivity of the furnace-cooled specimen scarecely increases at room temperature. Therefore, such an increase of the air-quenched specimen may be associated with the formation of small G.P. (1) aggregates that occurs during the plastic deformation, for such an effect was not observed in the case when the specimen was furnace-cooled. On the other hand, at −196°C in the air-quenched specimen, the rapid increase of resistivity continues to the range of large strain. The relation between $\Delta\rho$ and ε can be approximately expressed by $\Delta\rho=k\varepsilon^{1.1\sim1.2}$, where k is a constants. The results of the furnace-cooled specimen also showed a similar trend to increase. The diffusion of solute atoms which form G.P. (1) aggregates is appreciably suppressed at −196°C. So, in the case of −196°C, the most part of increase of $\Delta\rho$ in both specimens may be ascribed to the point imperfections, i.e. vacancies or interstitials created during the plastic deformation, because the point imperfections can hardly recover at such a low temperature. This fact may also be confirmed from the following two reasons. (1) A similar relation between $\Delta\rho$ and ε has been found in pure metals, such as copper, experimentally and theoretically.[4,5] In this case, the $\Delta\rho$ is attributed to the vacancies formed during the plastic deformation. However, it must be mentioned that the $\Delta\rho$ of the present investigation is appreciably larger than that of pure metals. (2) When the specimens tested at −196°C held at 20°C for a few minutes at the last stage of the deformation, the resistivity decreases to or below the $\Delta\rho$-ε curve for room temperature, as shown in the figure. This decrease may be understood to the caused by understood to be caused by the recovery of the point imperfections.

On Some Singular Solutions of the Tricomi Equation Relating to Transonic Flow

By J. B. Diaz

Institute for Fluid Dynamics and Applied Mathematics, University of Maryland, College Park, Maryland

(Received November 11, 1957)

In his interesting paper with the same title, Professor Kinzo Hida (Journal of the Physical Society of Japan, Vol. 10, No. 10, October 1955, 869–881) employs on page 871, equation (2.11), what he calls Cole's solution

$$\Gamma_{-}(z, v, z_1) = \tfrac{1}{4}(\tfrac{2}{3}zz_1)^{1/3}\int_0^\infty e^{-\alpha v}J_{-1/3}(\alpha z)J_{-1/3}(\alpha z_1)d\alpha\,. \tag{1}$$

Professor Hida has probably overlooked that Cole himself, in his paper (Journal of Mathematics and Physics, Vol. 30, No. 2, July 1951, 79–93), in a footnote on page 85, attributes this solution to A. Weinstein. Incidentally, Cole's footnote contains a misprint, he means Weinstein's formula (19), *not* (24). Moreover, Cole refers also to another paper of Weinstein (Proceedings Naval Ordnance Laboratory Aeroballistic Research Symposia, 1950, 73–81) in which Weinstein applies his formula and other more general formulas to the problem of the flow around a wedge.

In view of these facts it may be of interest to mention some additional literature on the same subject, part of which appeared in purely mathematical journals:

A. Weinstein, (Proceedings of the Fourth Symposium in Applied Mathematics of the American Mathematical Society, held June 1951 at the University of Maryland, published 1953, pages 167–178);

L. Trilling and K. Walker, Jr., (Journal Math. Phys., Vol. 32, 1953, 72–79, specially page 74);

P. Germain and R. Bader, (Bulletin Société Mathématique de France, Vol. 81, 1953, 145–174, specially page 161);

P. Germain, (Communications on Pure and Applied Mathematics, Vol. 7, 1954, 117–144);

A. G. Mackie and D. C. Pack, (Journal of Rational Mechanics and Analysis, Vol. 4, 1955, 177–199).

Several other expressions can be given for such singular solutions, see, for instance J. B. Diaz and A. Weinstein, (Studies in Mathematics and Mechanics presented to Richard von Mises, Academic Press, New York, 1954, 97–102).
